The name was probably taken from the kingdom of Morocco, whence the manner of preparing it was borrowed, which is this: the skins being first dried in the hair, are steeped in water three days and nights; then stretched on a tanner's horse, beaten with a large knife, and steeped afresh in water every day: they are then thrown into a large vat in the ground, full of water, where quicklime has been slaked, and there lie fifteen days; whence they are taken, and again returned every night and morning. They are next thrown into a fresh vat of lime and water, and shifted night and morning for fifteen days longer; then rinsed in clear water, and the hair taken off on the leg with the knife, returned into a third vat, and shifted as before for eighteen days; steeped twelve hours in a river, taken out, rinsed, put in pails, where they are pounded with wooden pestles, changing the water twice; then laid on the horse, and the flesh taken off; returned into pails of new water, taken out, and the hair-side scraped; returned into fresh pails, taken out, and thrown into a pail of a particular form, having holes at bottom: here they are beaten for the space of an hour, and fresh water poured on from time to time; then being stretched on the leg, and scraped on either side, they are returned into pails of fresh water, taken out, stretched and sewed up all around in manner of bags, leaving out the hinder legs as an aperture for the conveyance of a certain mixture.

The skins thus sewed are put in lukewarm water, where dogs excrements have been dissolved. Here they are stirred with long poles for half an hour, left at rest a dozen, taken out, rinsed in fresh water, and filled by a tunnel with a preparation of water and sumac, mixed and heated over the fire till ready to boil; and, as they are filled, the hind legs are sewed up to stop the passage. In this state they are let down into the vessel of water and sumac, and kept stirring for four hours successively; taken out and heaped on one another; after a little time their sides are changed, and thus they continue an hour and a half till drained. This done, they are loosened, and filled a second time with the same preparation, sewed up again, and kept stirring two hours, piled up and drained as before. This process is again repeated, with this difference, that they are then only stirred a quarter of an hour; after which they are left till next morning, when they are taken out, drained on a rack, unsewed, the sumac taken out, folded in two from head to tail, the hair-side outwards, laid over each other on the leg, to perfect their draining, stretched out and dried; then trampled under foot by two and two, stretched on a wooden table, what flesh and sumac remains scraped off, the hair-side rubbed over with oil, and that again with water.

They are then wrung with the hands, stretched, and pressed tight on the table with an iron-instrument like that of a currier, the flesh side uppermost; then turned, and the hair-side rubbed strongly over with a handful of rushes, to squeeze out as much of the oil remaining as possible. The first curse of black is now laid on the hair-side, by means of a lock of hair twisted and steeped in a kind of black dye, prepared of sour beer, wherein pieces of old rusty iron have been thrown. When half-dried in the air, they are stretched on a table, rubbed over every way with a paumelle, or wooden-toothed instrument, to raise the grain, over which is past a light couch of water, then sleeked by rubbing them with rushes prepared for the purpose. Thus sleeked, they have a second couche of black, then dried, laid on the table, rubbed over with a paumelle of cork, to raise the grain again; and, after a light couche of water, sleeked over anew; and to raise the grain a third time, a paumelle of wood is used.

After the hair-side has received all its preparations, the flesh-side is pared with a sharp knife for the purpose: the hair-side is strongly rubbed over with a woollen cap, having before given it a gloss with barberries, citron, or orange. The whole is finished by raising the grain lightly, for the last time, with the paumelle of cork; so that they are now fit for the market.

Manner of preparing red MOROCCO: after steeping, stretching, scraping, beating, and rinsing the skins, as before, they are at length wrung, stretched on the leg, and passed after each other into water where alum has been dissolved. Thus alumed, they are left to drain till morning, then wrung out, pulled on the leg, and folded from head to tail, the flesh inwards.

In this state they receive their first dye, by passing them after one another into a red liquor prepared with laque, and some other ingredients, which the marowquineers keep a secret. This they repeat again and again, till the skins have got their first colour; then they are rinsed in clear water, stretched on the leg, and left to drain twelve hours; thrown into water through a sieve, and stirred incessantly for a day with long poles; taken out, hung on a bar across the water all night, white against red, and red against white, and in the morning the water stirred up, and the skins returned into it for twenty-four hours.

MORTALITY, *Bills of*, accounts of the numbers of deaths or burials in any parish or district. The establishment of registers of this kind in Great Britain, was occasioned by the plague, and an abstract of them was published weekly, to shew the increase or decrease of the disorder, that individuals might judge of the necessity of removal, or of taking other precautions against it, and government be informed of the propriety or success on any public measures relating to the disorder. The first directions for keeping registers of births and burials were contained in the injunctions to the clergy, issued in the year 1538, which not being properly attended to, were enforced in 1547, and again in the beginning of the reign of Elizabeth, who also appointed a protestation to be made by the clergy, in which, among other things, they promise to keep the register-book in a proper manner. One of the canons of the church prescribes very minutely in what manner entries are to be made in the parish-registers, and orders an attested copy of the register of each successive year to be annually transmitted to the bishop of the diocese or his chancellor, and to be preserved in the bishop's registry. These registers have only been occasionally communicated to the public, and that without sufficient particulars to supply much information; but in London, and the surrounding parishes, the parish-clerks are required to make a weekly return of burials, with the age and disease of which the person died; a summary of which account is published weekly; and on the Thursday before Christmas-day, a general account is made up for the whole year. These accounts of christenings and burials, taken by the company of parish clerks of London, were began 21st Dec. 1592, but were not made public till 1594; and towards the end of the following year, upon the ceasing of the plague, they were discontinued; at this time the London bills of mortality comprehended but 109 parishes. In 1603, the weekly bills of mortality were resumed, and have been regularly continued ever since; the number of parishes included in them has been increased at different times, and at present is 146.

Bills of mortality, especially such as give the ages of the dead and the disorders of which they died, furnish much useful information; they shew the different degrees of healthiness of seasons or districts, the progress of population, and the probabilities of the duration of human life in any part of the usual term of existence; they are the foundations on which all tables of the value of annuities on lives, or depending on survivorship, have been constructed.

In 1662, Mr. John Graunt published some ingenious observations on the London Bills of Mortality, which were much enlarged in subsequent editions. Sir William Petty, in 1683, made considerable use of the information afforded by them, in his Political Arithmetic. In 1742, Mr. T. Simpson published his Treatise on Annuities, in which he inserted a table formed by Mr. Smart from the London bills of mortality, with some corrections which appeared necessary: in 1746, Mr. De Parcieux, in an Essai sur les Probabilités de la Vie humaine, made some objections to Mr. Simpson's alterations in the London bills, but without sufficient foundation; and in 1752, Mr. Simpson, in a supplement to his Treatise on Annuities, made use of the same table from the London bills, but adapted to a different radix. In 1769, Dr. Price published his treatise on Reversionary Payments, in which, particularly in the subsequent editions, many valuable observations are to be found on the bills of mortality of different places, and very accurate tables are given of the expectation of life, and the value of annuities, according to these bills.

Dr. Price remarks, that in every place which just supports itself in the number of its inhabitants, without any recruits from other places; or where, for a course of years, there has been no increase or decrease, the number of persons dying every year at any particular age, and above it, must be equal to the number of the living at that age. The number, for example, dying every year, at all ages, from the beginning to the utmost extremity of life, must, in such situation, be just equal to the whole number born every year. And for the same reason, the number dying every year at one year of age and upwards, at two years of age and upwards, at three and upwards, and so on, must be equal to the numbers that attain to those ages every year; or, which is the same, to the numbers of the living at those ages. It is obvious, that unless this happens, the number of inhabitants cannot remain the same; it follows, therefore, that in a town or country, where there is no increase or decrease, bills of mortality which give the ages at which all die, will shew the exact number of inhabitants; and also the exact law, according to which human life wastes in that town or country. In order to find the number of inhabitants, the mean numbers dying annually at every particular age and upwards, must be taken as given by the bills, and placed under one another in the order of the second column: see Table I, article EXPECTATION. These numbers will be the numbers of the living at 1, 2, 3, &c. years of age; and, consequently, the sum, diminished by half the number born annually, will be the whole number of inhabitants.

The bills of mortality, in some parts of Great Britain, are known to be materially defective; the deficiencies may chiefly be ascribed to the following circumstances: 1. Many congregations of dissenters, inhabiting towns, have their own peculiar burying-grounds; as have the Jews, and the Roman Catholics, who reside in London. 2. Some persons, from motives of poverty or convenience, inter their dead without any religious ceremony; this is known to happen in the metropolis, in Bristol, and Newcastle-upon-Tyne, and may happen in a few other large towns. 3. Children who die before baptism are interred without any religious ceremony, and consequently are not registered. 4. Negligence may be supposed to cause some omissions in the registers, especially in those small benefices, where the officiating minister is not resident. 5. Many persons employed in the army and in navigation die abroad, and consequently their burials remain unregistered. Whatever may be the total number of deaths and burials, which from these several circumstances are not brought to account, it has been computed that about 5000 of them may be attributed to the metropolis, and a large portion of the rest may be ascribed to the other great towns, and to Wales, where the registers are less carefully kept than in England.

The annual amount of the burials, as collected conformably to the population act, authorizes a satisfactory inference of diminishing mortality in England since the year 1780; the number of marriages and baptisms, indicates that the existing population in 1801, was to that of 1780, as 117 to 100, while the amount of registered burials remained stationary during the same period; the first five years of which, as well as the last five years, and all the 21 years taken together, equally averaged about 186,000 per annum.

The whole number of baptisms, collected for the purposes of the population act, was 6,436,110; of these 3,285,188 were males, and 3,150,922 females; so that the baptisms of males were 10,426 to 10,000 baptisms of females. The whole number of the burials appeared to be 5,165,844; of which 2,575,762 were males, and 2,590,082 females, so that the burials of males were 9,944 to 10,000 burials of females. It may be interred hence, that of 10,426 males born in England, only 9,944 die at home; therefore, about one in twenty-two dies abroad in the employments of war and commerce; a proportion which strongly marks the enterprising character of the nation.

MORTAR-PIECE, a short piece of ordnance, considerably thick and wide; serving to throw bombs, carcases, fire-pots, &c. See GUNNERY.

MORTGAGE, signifies a pawn of land or tenement, or any thing immoveable, laid or bound for money borrowed, to be the creditor's for ever, if the money is not paid at the day agreed upon; and the creditor holding land and tenement upon this bargain, is called tenant in the mortgage. He who pledges this pawn, or gage, is called the mortgageor, and he who takes it, the mortagee.

The last and best improvement of mortgages seems to be, that in the mortgage-deed of a term for years, or in the assignment thereof, the mortgageor should covenant for himself and his heirs, that if default is made in the payment of the money at the day, then he and his heirs will, at the costs of the mortgagee and his heirs, convey the freehold and inheritance of the mortgaged lands to the mortgagee and his heirs, or to such person or persons (to prevent merger of the term) as he or they shall direct and appoint: for the reversion, after a term of fifty or a hundred years, being little worth, and yet the mortgagee for want thereof continuing but a termer, and subject to a forfeiture, &c. and not capable of the privileges of a freeholder; therefore when the mortgageor cannot redeem the land, it is but reasonable the mortgagee should have the whole interest and inheritance of it to dispose of it as absolute owner. 3 Bac. Abr. 633.

Although after breach of the condition, an absolute fee-simple is vested at common law in the mortgagee; yet a right of redemption being still inherent in the land, till the equity of redemption is foreclosed, the same right shall descend to, and is invested in, such persons as had a right to the land, in case there had been no mortgage or incumbrance whatsoever; and as an equitable performance as effectually defeats the interests of the mortgage, as the legal performance does at common law, the condition still hanging over the estate till the equity is totally foreclosed; on this foundation it has been held that a person who comes in under a voluntary conveyance, may redeem a mortgage; and though such right of redemption is inherent in the land, yet the party claiming the benefit of it, must not only set forth such right, but also shew that he is the person entitled to it. Hard. 465.

But if a mortgage is forfeited, and thereby the estate absolutely vested in the mortgagee at common law, yet a court of equity will consider the real value of the tenements, compared with the sum borrowed. And if the estate is of greater value than the sum lent thereon, they will allow the mortgageor, at any reasonable time, to recal or redeem the estate, paying to the mortgagee his principal, interest, and costs. This reasonable advantage, allowed to the mortgageors, is called the equity of redemption. 2 Black. 159.

It is a rule established in equity, analogous to the statute of limitation, that after twenty years possession of the mortagee, he shall not be disturbed, unless there are extraordinary circumstances; as in the case of femes covert, infants, and the like. 3 Atk. 313.

MORTISE, or *Mortoise*, in carpentry, &c. a kind of joint, wherein a hole of a certain depth is made in a piece of timber, which is to receive another piece called a tenon.

MORTMAIN, signifies an alienation of lands and tenements, to any guild, corporation, or fraternity, and their successors, as bishops, parsons, vicars, &c. which may not be done without the king's licence, and the lord of the manor; or of the king alone, if it is immediately holden of him.

But in order to prevent any imposition in respect to the disposal of lands to charitable uses, which might arise in a testator's last hours, and in some measure, from political principles, to restrain devises in mortmain, or the too great accumulation of land in hands where it lies dead, and not subject to change possession, it is provided by stat. 9 G. II. c. 36, (called the statute of mortmain), that no manors, lands, tenements, rents, advowsons, or other hereditaments, corporeal or incorporeal, whatsoever, nor any sum or sums of money, goods, chattels, stocks in the public funds, securities for money, or other personal estate whatsoever, to be laid out or disposed of in the purchase of any lands, tenements, or hereditaments, shall be given, limited, or appointed by will, to any person or persons, bodies politic or corporate, or otherwise for any estate or interest whatsoever; or any ways charged or incumbered by any person or persons whatsoever, in trust, or for the benefit of any charitable use whatsoever; but such gift shall be by deed indented, sealed and delivered in the presence of two or more credible witnesses, twelve calendar months at least before the debt of such donor, and be inrolled in the high court of chancery within six calendar months after execution for the charitable use intended; and be without any power of revocation, reservation, or trust, for benefit of the donor. And all gifts and appointments whatsoever, of any lands, tenements, or other hereditaments, or of any estate or interest therein, or of any charge or incumbrance affecting or to affect any lands, tenements, or hereditaments, or any personal estate to be laid out in the purchase of any lands, tenements, or hereditaments, or any estate or interest therein, or of any charge or incumbrance affecting or to affect the same, to or in trust for any charitable use whatsoever, made in any other manner than is directed by this act, shall be absolutely null and void. But the two universities, their colleges, and the scholars upon the foundation of the colleges at Eton, Westminster, and Winchester, are excepted out of this act; but with this proviso, that no college shall be at liberty to purchase more advowsons than are equal in number to one moiety of the fellows or students upon the respective foundations.

MORUS, the MULBERRY-TREE, a genus of the tetrandria order, in the monœcia class of plants; and in the natural method ranking under the 53d order, scabridæ. The male calyx is quadripartite; and there is no corolla: the female calyx is tetraphyllous; there is no corolla; two styles; the calyx like a berry, with one seed. There are seven species, viz. 1. The nigra, or common black-fruited mulberry-tree, rises with an upright, large, rough trunk, dividing into a branchy and very spreading head, rising 20 feet high, or more. 2. The alba, or white mulberry-tree, rises with an upright trunk, branching 20 or 30 feet high. There is a variety with purplish fruit. 3. The papyrifera, or paper mulberry-tree of Japan, grows 20 or 30 feet high; having large palmated leaves, some trilobate, others quinquelobed; and monœcious flowers, succeeded by small back fruit. 4. The rubra, or red Virginia mulberry-tree, grows 30 feet high; and has large reddish berries. 5. The tinctoria, dyer's mulberry, or fustic, has oblong leaves more extended on one side at the base, with axillary thorns. It is a native of Brasil and Jamaica. 6. The tartarica, or Tartarian mulberry, has ovate oblong leaves, equal on both sides, and equally serrated. It abounds on the banks of the Wolga and the Tanais. 7. the Indica, or Indian mulberry, has ovate oblong leaves, equal on both sides, but unequally serrated.

The last three species are tender plants in this country; but the four first are very hardy, and succeed in any common soil and situation. The leaves are generally late before they come out, the buds seldom beginning to till the middle or towards the latter end of May, according to the temperature of the season; and when these trees, in particular, begin to expand their foliage, it is a good sign of the near approach of fine warm settled weather; the white mulberry, however, is generally forwarder in leafing than the black.

Considered as fruit-trees, the nigra is the only proper sort to cultivate here; the trees being not only the most plentiful bearers, but the fruit is larger and much finer-flavoured than that of the white kind, which is the only other sort that bears in this country. The three next species are chiefly employed to form variety in our ornamental plantations; though abroad they are adapted to more useful purposes. The wood of the mulberry-tree is yellow, tolerably hard, and may be applied to various uses in turnery and carving: but in order to separate the bark, which is rough, thick, thready, and fit for being made into ropes, it is proper to steep the wood in water.

Mulberry-trees are noted for their leaves affording the principal food of that valuable insect the silkworm. The leaves of the alba, or white species, are preferred for this purpose in Europe; but in China where the best silk is made the worms are said to be fed with those of the morus tartarica. The advantages of white mulberry-trees are not confined to the nourishment of worms: they may be cut every three or four years like sallows and poplar trees, to make faggots; and the sheep eat their leaves in winter, before they are burnt. This kind of food, of which they are extremely fond, is very nourishing; it gives a delicacy to the flesh, and a fineness and beauty to the wool.

The papyrifera, or paper-mulberry, is so called from the paper chiefly used by the Japanese being made of the bark of its branches. The leaves of this species also serve for food to the silkworm, and it is now cultivated with success in France. It thrives best in sandy soils, grows faster than the common mulberry, and at the same time is not injured by the cold. M. de la Bouviere affirms that he procured a beautiful vegetable silk from the bark of the young branches of this species of mulberry, which he cut while the tree was in sap, and afterwards beat and steeped. The women of Louisiana procure the same kind of production from the shoots which issue from the stock of the mulberry, and which are four or five feet high. After taking off the bark, they dry it in the sun, and then beat it that the external part may fall off; and the internal part, which is fine bark, remains entire. This is again beaten, to make it still finer: after which they bleach it with dew. It is then spun, and various fabrics are made from it, such as nets and fringes: they even sometimes weave it, and make it into cloth. The finest sort of cloth among the inhabitants of Otaheite and others of the South Sea islands, is made of the bark of this tree.

The tinctoria is a fine timber-tree, and a principal ingredient in most of our yellow dyes, for which it is chiefly imported into Europe. The berries are sweet and wholesome; but not much used, except by the winged tribe, by whose care it is chiefly planted.

MOSAIC, or *mosaic-work*, an assemblage of little pieces of glass, marble, precious stones, &c. of various colours, cut square and cemented on a ground of stucco, in such a manner as to imitate the colours of painting.

MOSCHUS, musk, a genus of quadrupeds of the order pecora: the generic character is, horns none; front teeth in the lower jaw eight; tusks solitary, in the upper jaw exserted.

1. Moschus moschiferus, Tibetian musk. The musk is one of those quadrupeds whose true form and natural history appear to have continued in great obscurity long after the introduction and general use of the celebrated perfume which it produces. To the antients it was unknown, and was first mentioned by the Arabians, whose physicians used the drug in their practice. The animal was by some considered as a kind of goat, by others as a species of deer or antelope, and was, of course, supposed to be a horned animal; nor was it till about the decline of the seventeenth century that a tolerably accurate description or figure was to be found.

The size and general appearance of this animal resemble those of a small roebuck. It measures about three feet three inches in length, about two feet three inches in height from the top of the shoulders to the bottom of the fore-feet, and two feet nine inches from the top of the haunches to the bottom of the hind feet. The upper jaw is considerably longer than the lower, and is furnished on each side with a curved tusk about two inches long. These tusks are of a different form from those of any other quadruped; being sharp-edged on their inner or lower side, so as to resemble, in some degree, a pair of small crooked knives: their substance is a kind of ivory, as in the tusks of the babyrussa and some other animals.

The general colour of the whole body is a kind of deep iron-grey; the tips of the hairs being of a ferruginous cast, the remainder blackish, growing much paler or whitish towards the roots. See Plate Nat. Hist. fig. 279.

The female is smaller than the male, and wants the tusks: it has also two small teats.

They are hunted for the sake of their well-known perfume: which is contained in an oval receptacle about the size of a small egg, hanging from the middle of the abdomen, and peculiar to the animal. This receptacle is found constantly filled with a soft, unctuous, brownish substance, of the most powerful and penetrating smell; and which is no other than the perfume in its natural state. As soon as the animal is killed, the hunters cut off the receptacle or musk-bag, and tie it up ready for sale. The animals must of necessity be extremely numerous in some parts, since we are assured by Tavernier, the celebrated merchant and traveller, that he purchased, in one of his Eastern journeys, no less than seven thousand six hundred and seventy-three musk-bags.

So violent is the smell of musk, when fresh-taken from the animal, or from quantities put up by the merchants for sale, that it has been known to force the blood from the nose, eyes, and ears, of those who have imprudently inhaled its vapours.

As musk is an expensive drug, it is frequently adulterated by various substances; and we are assured that pieces of lead have been found in some of the receptacles, inserted in order to increase the weight. The smell of musk is so remarkably diffusive, that every thing in its neighbourhood becomes strongly infected with it; even a silver cup that has had musk in it does not part with the scent, though other odours are in general very readily discharged from metallic substances.

As a medicine it is held in high estimation in the Eastern countries, and has now been introduced into pretty general use among ourselves, especially in those disorders which are commonly termed nervous; and in convulsive and other cases, it is often exhibited in pretty large doses with great success.

2. Moschus Indicus, or the Indian musk. This species is said to be rather larger than the common or Tibetian musk, of the colour mentioned in the specific character, with the head shaped like that of a horse, upright oblong ears, and slender legs. It is a native of India.

3. Moschus pygmæus, or the pygmy musk, is considerably smaller than a domestic cat,

measuring little more than nine inches from the nose to the tail. Its colours is bright bay, white beneath and on the insides of the thighs. Its shape is beautiful, and the legs are so slender as not to exceed the diameter of a swan-quill; the head is rather large, and the aspect mild. It is a native of many parts of the East Indies and the Indian islands, and is said to be most common in Java, where the natives catch great numbers in snares, and carry them to the markets in their cages for sale. According to Mr. Pennant they may be purchased at so low a rate as two pence halfpenny a piece. There are three other species.

MOSQUE, a temple or place of religious worship among the Mahometans.

All mosques are square buildings, generally built with stone; before the chief gate there is a square court, paved with white marble, and low galleries round it, whose roof is supported by marble pillars. In these galleries the Turks wash themselves before they go into the mosque. In each mosque there are a great number of lamps; and between these hang many crystal rings, ostriches' eggs, and other curiosities, which, when the lamps are lighted, make a fine shew. As it is not lawful to enter the mosques with shoes or stockings on, the pavements are covered with pieces of stuff sewed together, each being wide enough to hold a row of men kneeling, sitting, or prostrate. The women are not allowed to enter the mosques, but stay in the porches without. About every mosque there are six high towers, called minarets, each of which has three little open galleries, one above another: these towers, as well as the mosques, are covered with lead, and adorned with gilding and other ornaments; and from thence, instead of a bell, the people are called to prayer by certain officers appointed for that purpose. Most of the mosques have a kind of hospital belonging to them, in which travellers, of what religion soever, are entertained during three days. Each mosque has also a place called tarbé, which is the burying-place of its founders; within which is a tomb six or seven feet long, covered with green velvet or satin, at the ends of which are two tapers, and round it several seats for those who read the koran, and pray for the souls of the deceased.

MOSS. See Muscus.

MOTACILLA, the *wagtail* and *warbler*, a genus of birds of the order of passeres, distinguished by a straight weak bill of a subulated figure, a tongue lacerated at the end, and very slender legs.

1. The alba, or white wagtail, frequents the sides of ponds and small streams, and feeds on insects and worms. The head, back, and upper and lower side of the neck as far as the breast, are black; in some the chin is white, and the throat marked with a black crescent; the breast and belly are white. The tail is very long, and always in motion. Mr. Willughby observed, that this species shifts its quarters in the winter, moving from the north to the south of England during that season. In spring and autumn it is a constant attendant on the plough, for the sake of the worms thrown up by that instrument.

2. The flava, or yellow wagtail, migrates in the north of England, but in Hampshire continues the whole year. The male is a bird of great beauty; the breast, belly, thighs, and vent-feathers, being of a most vivid and lovely yellow. The colours of the female are far more obscure than those of the male: it wants also those black spots on the throat.

3. The regulus, or gold-crested wren, is a native of Europe, and of the correspondent latitudes of Asia and America. It is the least of all the European birds, weighing only a single drachm. Its length is about four inches and a half, and the wings when spread out measure little more than six inches. On the top of its head is a beautiful orange-coloured spot, called its crest, which it can hide at pleasure; the margins of the crest are yellow, and it ends in a pretty broad black line; the sides of the neck are of a beautiful yellowish-green; the eyes surrounded with a white circle; the neck and back of a dark green mixed with yellow. In America it associates with the titmice, running up and down the bark of lofty oaks with them, and collecting its food in their company, as if they were all of one brood. It feeds on insects lodged in the winter dormitories in a torpid state. It is said to sing very melodiously.

4. The sutoria, or taylor-bird, is a native of the East Indies. It is remarkable for the art with which it makes its nest, seemingly in order to secure itself and its young, in the most perfect manner possible, against all danger from voracious animals. It picks up a dead leaf, and sews it to the side of a living one: its slender bill is the needle, and its thread is formed of some fine fibres; the lining is composed of feathers, gossamer, and down. The colour of the bird is light yellow; its length three inches, and its weight only three-sixteenths of an ounce; so that the materials of the nest and its own size are not likely to draw down a habitation depending on so slight a tenure.

5. The lucinia, or nightingale, exceeds in size the hedge-sparrow. The bill is brown; the irides are hazel; the head and back pale tawny, dashed with olive; the tail is of a deep tawny red; the under parts pale ash-colour, growing white towards the vent; the quills are cinereous brown. The male and female are very similar. This bird, the most famed of the feathered tribe for the variety, length, and sweetness of its notes, is supposed to be migratory. It is met with in Siberia, Sweden, Germany, France, Italy, and Greece. Hasselquist speaks of it as being in Palestine, and Fryer ascertains its being found about Chulminor in Persia; it is also spoken of as a bird of China, Kamtschatka, and Japan; at which last place they are much esteemed, and sell dear; as they are also at Aleppo, where they are "in great abundance kept tame in houses, and let out at a small rate to such as choose it in the city, so that no entertainment is made in the spring without a concert of these birds."

They are solitary birds, never uniting into even small flocks; and in respect to the nests, it is very seldom that two are found near each other. The female builds in some low bush or quickset edge, well covered with foliage, for such only this bird frequents; and lays four or five eggs of a greenish-brown. The nest is composed of dry leaves on the outside, mixed with grass and fibres, lined with hair or down within, though not always alike. The female alone sits on and hatches the eggs, while the male not far off regales her with his delightful song; but as soon as the young are hatched, he commonly leaves off singing, and joins with the female in the task of providing for and feeding them. After the young can provide for themselves, the old female provides for a second brood, and the song of the male recommences. They have been known to have three broods in a year, and in the hot countries even four. These birds are often brought up from the nest for the sake of their song. They are likewise caught at their first coming over; and though old birds, yet by management can be made to bear confinement, and to sing equally with those brought up from the nest. None but the vilest epicure, as Mr. Latham remarks, would think of eating these charming songsters: yet we are told that their flesh is equal to that of the ortolan, and they are fatted in Gascony for the table.

6. The medularis, or hedge-sparrow, a well-known bird, has the back and wing-coverts of a dusky hue, edged with reddish-brown; rump of a greenish-brown; throat and breast of a dull ash-colour; the belly a dirty white; and the legs of a dull flesh-colour. The note of this bird would be thought pleasant, did it not remind us of the approach of winter; beginning with the first frosts, and continuing till a little time in spring. Its often repeating the word tit, tit, tit, has occasioned its being called titling; a name it is known by in many places.

7. The phœnicurus, or redstart, is somewhat less than the redbreast; the forehead is white; the crown of the head, hind part of the neck, and back, are deep blue-grey; the cheeks and throat black; the breast, rump, and sides, red; and the belly is white; the two middle tail-feathers are brown; the rest red; and the legs are black. The wings are brown in both sexes.

This bird is migratory; coming hither in spring, and departing in autumn about October. It is not so shy as many birds in respect to itself; for it approaches habitations, and frequently makes its nest in some hole of a wall where numbers of people pass by frequently; yet it is content, if no one meddles with the nest. This bird frequently wags its tail; but does it sideways, like a dog, when he is pleased, and not up and down like the wagtail. It is with difficulty that these birds are kept in a cage; nor will they submit to it by any means if caught old. Their song has no great strength; yet it is agreeable enough; and they will, if taught young, imitate the notes of other birds, and sing by night frequently as well as in the day-time.

8. The rubecula, or redbreast, is universally known. It abounds in Burgundy and Lorraine, where numbers are taken for the table, and thought excellent. It builds not far from the ground if in a bush; though sometimes it fixes on an out-house, or retired part of some old building. The nest is composed of dried leaves, mixed with hair and moss, and lined with feathers. The eggs are of a dusky white, marked with irregular reddish spots; and are from three to seven in number. The young, when full-feathered, may be taken for a different bird, being spotted all over. The first rudiments of the red break forth on the breast about the end of August; but it is quite the end of September before they come to the full colour. Insects are

their general food; but in defect of these they will eat many other things. No bird is so tame and familiar as this; closely attending the heels of the gardener when he is using his spade, for the sake of worms; and frequently in winter entering houses where windows are open, when they will pick up the crumbs from the table while the family is at dinner. Its familiarity has caused a petty name to be given it in several countries. The people about Bornholm call it Tommi-liden; in Norway, Peter-ronsmad; the Germans, Thomas-gierdet; and we, the Robin-red-breast.

9. The œnanthe, or wheatear, is in length five inches and a half. The top of the head, hind part of the neck, and back, are of a blueish grey; and over the eye a streak of white; the under parts of the body yellowish-white: the breast is tinged with red; and the legs are black. This bird is met with in most parts of Europe, even as far as Greenland: and specimens have also been received from the East Indies. It visits England annually in the middle of March, and leaves us in September. It chiefly frequents heaths. The nest is usually placed under shelter of some turf, clod, stone, or the like, always on the ground, and not unfrequently in some deserted rabbit-burrow. It is composed of dry grass or moss, mixed with wool, fur of the rabbit, &c. or lined with hair and feathers. The eggs are from five to eight in number, of a light blue, with a deeper-blue circle at the large end. The young are hatched the middle of May. In some parts of England these birds are in vast plenty. About Eastbourn in Sussex they are taken in snares made of horsehair placed beneath a long turf: being very timid birds, the motion of a cloud, or the appearance of a hawk, will drive them for shelter into these traps, and so they are taken. The numbers annually ensnared in that district alone amount to about 1840 dozen, which usually sell at sixpence per dozen. Quantities of these are eaten on the spot by the neighbouring inhabitants; others are picked, and sent up to the London poulterers; and many are potted, being as much esteemed in England as the ortolan on the continent. Their food is insects only; though in rainy summers they feed much on earth-worms, whence they are fattest in such seasons.

10. The cyanea, or superb warbler, a most beautiful species, is five inches and a half long. The bill is black; the feathers of the head are long, and stand erect like a full crest; from the forehead to the crown they are of a bright blue; thence to the nape, black like velvet; through the eyes from the bill there runs a line of black; and beneath the eye springs a tuft of the same blue feathers; beneath which, and on the chin, it is of a deep blue, almost black, and feeling like velvet. The hind part of the neck, and upper parts of the body and tail, are of a deep blue-black, the under pure white; the wings are dusky; the shafts of the quills chesnut; the legs are dusky brown; the claws black. It inhabits Van Diemen's Land, the most southern part of New Holland. The female of this species, is discovered to be entirely destitute of all the fine blue colours, both pale and dark, by which the male is adorned, except that there is a very narrow circle of azure round each eye, apparently on the skin only.

11. The troglodytes, or wren, is a very small species, in length only three inches and three quarters, though some have measured four inches. It generally carries the tail erect. This minute bird is found throughout Europe; and in England it defies our severest winters. Its song is much esteemed, being, though short, a pleasing warble, and much louder than could be expected from the size of the bird; it continues throughout the year.

The sylvia builds in low bushes, and lays five pale-green eggs, sprinkled with reddish spots. See Plate Nat. Hist. fig. 271.

Above 150 other species, besides varieties, are enumerated by ornithologists.

MOTE, in law-books, signifies court, meeting, or convention, as a ward-mote, burghmote, swain-mote, &c.

MOTH. See PHALÆNA.

MOTION, has been defined to be "a change of place," or the act by which a body corresponds with different parts of space at different times.

We are principally acquainted with two sorts of motion in the beings that surround us; one is the motion by which an entire body is transferred from one place to another, as that of a stone when it falls, or of a ship under sail. It is this species of motion which most frequently comes under our observation, and with which we are best acquainted. But, besides this, there is another kind of motion, which, though not so obvious, is yet not less common nor important. This is a motion of the parts of bodies among themselves, which though sometimes the object of our senses, yet in other cases we require the aid of reflection to be convinced of its existence. It is by this imperceptible motion that plants and animals grow, and by which the greatest number of the compositions and decompositions throughout the globe take place. We may form some idea of this, by observing the continual motion of the light particles which sometimes float about in water, when it is held in the rays of the sun, which proves, that the parts of the water themselves are in constant motion. But if we reflect a little, we shall discover that the particles of the most solid bodies are also continually changing their situations. Heat expands, and cold contracts, the size of all bodies; now, we know from experience, that the temperature of bodies is constantly varying, consequently, the particles must be in continual agitation, in order to adapt themselves to the size of the body.

The communication of motion from one body to another, though a fact with which we are well acquainted, we are equally incapable of accounting for. It is, however, of the utmost importance in mechanics, which is indeed an art derived from the study of its laws. In considering motion, several circumstances must be attended to:

1. The force which impresses the motion. 2. The quantity of matter in the moving body. 3. The velocity and direction of the motion. 4. The space passed over by the moving body. 5. The time employed in going over this space. 6. The force with which it strikes another body that is opposed to it.

In a mechanical sense, every body, by its inertia, resists all change of state. If at rest, it will not begin to move of itself; and if motion is communicated to it by another body, it will continue to move for ever uniformly, except it is stopped by an external agent. It is true, we do not see any instances of bodies continuing to move for ever, after being once put in motion; but the reason of this is, that all the bodies which we see are acted upon in such a manner, as to have their motion gradually destroyed by friction, or the rubbing of other bodies upon them. For if you diminish the friction by any means, the motion will continue much longer; but as it is impossible to destroy it entirely, it diminishes, and at last destroys, all motions on the surface of the earth. To put a body in motion, therefore, there must be a sufficient cause. These causes are called motive powers, and the following are those generally used in mechanics; the action of men and other animals, wind, water, gravity, the pressure of the atmosphere, and the elasticity of fluids and other bodies.

The velocity of motion is estimated by the time employed in moving over a certain space, or by the space moved over in a certain time. To ascertain the degree of this swiftness or velocity, the space run over must be divided by the time. For example: suppose a body moves over 1000 yards in 10 minutes, its velocity will be 100 yards per minute. If we would compare the velocity of two bodies A and B, of which A moves over 54 yards in 9 minutes, and B 96 yards in 6 minutes, the velocity of A will be to that of B, in the proportion of 6 (the quotient of 54 divided by 9) to 16 (the quotient of 96 divided by 6).

To know the space run over, the velocity must be multiplied by the time; for it is evident, that if either the velocity or the time is increased, the space run over will be greater. If the velocity is doubled, then the body will move over twice the space in the same time; or if the time is twice as great, then the space will be doubled; but if the velocity and time are both doubled, then will the space be four times as great.

It follows from this, that when two bodies move over unequal spaces in unequal times, their velocities are to each other as the quotients arising from dividing the spaces run over by the times. If two bodies move over unequal spaces in the same time, their velocities will be in proportion to the spaces passed over. And if two bodies move over equal spacss in unequal times, then their respective velocities will be inversely as the time employed; that is, if A in one minute, and B in two minutes, run over 100 yards, the velocity of A will be to that of B as 2 to 1.

A body in motion must every instant tend to some particular point. It may either tend always to the same point, in which case the motion will be in a straight line; or it may be continually changing the point to which its motion is directed, and this will produce a curvilinear motion.

If a body is acted upon only by one force, or by several in the same direction, its motion will be in the same direction in which the moving force acts; as the motion of a boat which a man draws to him with a rope. But if several powers, differently directed, act upon it at the same time, as it cannot obey them all, it will move in a direction somewhere between them.

This is what is called the composition and resolution of motion, and is of the utmost importance in mechanics.

Suppose a body A (Plate Miscel. fig. 163) to be acted upon by another body in the direction AB, while at the same time it is impelled by another in the direction AC, then it will move in the direction AD; and if the lines AB, AC, are made of lengths proportionate to the forces, and the lines CD, DB, drawn parallel to them, so as to complete the parallelogram ABDC, then the line which the body A will describe, will be the diagonal AD; and the length of this line will represent the force with which the body will move. It is evident, that if a body is impelled by equal forces acting at right angles to each other, that it will move in the diagonal of a square; but whatever may be the direction, or degree of force by which the two powers act, the above method will always give the direction and force of the moving body.

It follows from this, that if we know the effect which the joint action of two powers has upon a body, and the force and direction of one of them, it is easy to find that of the other. For, suppose AD to be the direction and force with which the body moves, and AB to be one of the impelling forces, then, by completing the parallelogram, the other power AC is found.

Instances in nature of motion produced by several powers acting at the same time, are innumerable. A ship impelled by the wind and tide is one well known. A paper kite, acted upon by the wind and the string, is another.

Motion is said to be accelerated, if its velocity continually increases; to be uniformly accelerated, if its velocity increases equally in equal times.

Motion is said to be retarded, if its velocity continually decreases: and to be uniformly retarded, if its velocity decreases equally in equal times.

If you suppose a body to be put in motion by a single impulse, and moving uniformly, to receive a new impulse in the same direction, its velocity will be augmented, and it will go on with the augmented velocity.

If at each instant of its motion it receives a new impulse, the velocity will be continually increasing; and if this impulse is always equal, the velocity will be uniformly accelerated.

The regularly increasing velocity with which a body falls to the earth, is an instance of accelerated motion, which is caused by the constant action of gravity. To illustrate this, let us suppose the time of descent of a falling body to be divided into a number of very small equal parts; the impression of gravity, in the first small instant, would make the body descend with a proportionate and uniform velocity; but in the second instant, the body receiving a new impulse from gravity, in addition to the first, would move with twice the velocity as before; in the third instant, it would have three times the velocity, and so on.

To illustrate the doctrine of accelerated motion, let us suppose that, in the triangle ABC (fig. Miscel. 164), AB expresses the time which a body takes to fall, and BC the velocity acquired at the end of the fall. Let AB be divided into a number of equal parts, indefinitely small, and from each of these divisions suppose lines, as DE, drawn parallel to BC; it is evident from what has been said, that those lines will express the velocities of the falling body in the several respective points of time, each being greater than the other, by a certain quantity of increase, which follows from the nature of the triangle. Now, the spaces described in the same time, are in proportion to the velocities; and the sum of the spaces described in all the small portions of time, is equal to the space described from the beginning of the fall. But the sum of all the lines parallel to BC, taken indefinitely near to each other, constitutes the area of the triangle. Therefore the space described by a falling body, in the time expressed by AB, with an uniformly accelerated velocity, of which the last degree is expressed by BC, will be represented by the area of the triangle ABC.

Let us now suppose that gravity ceased to act, and that the body moved during another portion of time, BF, equal to AB, with the acquired velocity represented by BC. As the space moved over is found by multiplying the velocity by the time, the rectangle CF will represent the space moved over in this second portion of time, which is twice the triangle ABC, and consequently twice the space is moved over with the accelerating velocity in the same time.

But if we suppose gravity still to act, besides the space CF, which it would have moved over by its acquired velocity, we must add the triangle CGH, for the effect of the constant action of gravity; therefore, in this second portion of time, the body moves over three times the space as in the first. In like manner, it may be easily seen by the figure, that in the next portion it would move over five times the space; in the next seven times, and so on, in arithmetical progression. And as the velocities of falling bodies are in proportion to the spaces run over, it follows, that the velocities in each instant increase, as the numbers 1, 3, 5, 7, 9, &c.

It follows from this, that the space run over is as the square of the time; that is, in twice the time, a body will fall with four times the velocity; in thrice the time, with nine times the velocity, &c. for, in the first time, there was but one space run over: the square of 1 is 1: at the end of the second time there are four spaces run over, one in the first, and three in the second; the square of 2 is 4; at the end of the third time there are nine spaces run over; the square of 3 is 9: and so on. This may be seen in the figure.

It is found by experiment, that a body falling from a height, moves at the rate of $16\frac{1}{12}$ feet in the first second; and, as has been shewn above, acquires a velocity of twice that, or $32\frac{1}{6}$ feet in a second. At the end of the next second, it will have fallen $64\frac{1}{3}$ feet, the space being as the square of the time: the square of 2 is 4, and 4 times $16\frac{1}{12}$ is $64\frac{1}{3}$. By the same rule you may find, that in the third second it will fall 144 feet; in the next 256 feet, and so on. It is to be understood, however, that by this velocity is meant what bodies would acquire, if they were to fall through a space where there was no air; for its resistance considerably diminishes their velocity in falling.

It has been already shewn, that if two forces act uniformly upon a body, they will cause it to move in a straight line; but if one of the forces is not uniform, but either accelerating or retarding, the moving body will describe a curve line. If a ball is projected from a cannon, it receives from it an impulse, which, if there was no resistance from the air, and if it was not acted upon by gravity, would cause it to move always in a straight line; but as soon as it leaves the mouth of the cannon, gravity acts upon it, and makes it change its direction. It then describes a curve, called a parabola. This is the foundation of the theory of projectiles, and the art of gunnery; but it is not now considered to be of so much importance as it formerly was, as it is found that the resistance of the air, and other causes, have so much effect upon projected bodies, that they describe curves very different from what they ought to do according to this theory; and therefore it is much less applicable to practice than otherwise it would be.

The force with which a body moves, or which it would exert upon another body opposed to it, is always in proportion to its velocity multiplied by its weight, or quantity of matter. This force is called the momentum of the body: for if two equal bodies move with different velocities, it is evident that their forces, or momenta, are as their velocities; and if two bodies move with the same velocity, their momenta are as the quantities of matter; therefore, in all cases, their momenta must be as the products of their quantities of matter, and their velocities. This rule is the foundation of mechanics.

In consequence of the vis inertiæ of matter, all motion produced by one force only acting upon a body, must be rectilinear; for it must receive some particular direction from the power that impressed it, and must retain that direction until it is changed by some other power. Whenever, therefore, we see a body moving in a curvilinear direction, we may be certain that it is acted upon by two forces at least. When one of the two forces ceases to act, the body will move again in a straight line. Thus a stone in a sling is moved round by the hand, while it is pulled towards the centre of the circle, which it describes, by the string: but when the string is let go, the stone flies off in a tangent to the circle.

Every body moved in a circle has a tendency to fly off from its centre, which endeavour of receding is called the centrifugal force: and it is opposed to the centripetal force; or that which, by drawing bodies towards the centre, makes them revolve in a curve. These two forces are called together central forces.

The centre of gravity of a body is that point about which all the parts of a body do in any situation exactly balance each other.

Hence, if a body is suspended or supported by this point, the body will rest in any position in which it is put. Also, whatever supports that point bears the weight of the whole body; and while it is supported, the body cannot fall. We may therefore consider the whole weight of a body as centred in this point.

The common centre of gravity of two or more bodies is the point about which they would equiponderate, or rest, in any position. If the centre of gravity of two bodies, A and B, (Plate Miscel. fig. 165) is connected by the right line AB, the distances AC and BC, from the common centre of gravity C, are reciprocally as the weights of the bodies A and B, that is, AC : BC : B : A.

If a line is drawn from the centre of gravity of a body, perpendicular to the horizon, it is called the line of direction; because it is the line that the centre of gravity would describe if the body fell freely.

It is the property of this line, that while it falls within the base upon which the body stands, the body cannot fall; but if it fall without the base, the body will tumble. Thus the inclining body ABCD, (fig. 166) whose centre of gravity is E, stands firmly on its base CDIK, because the line of direction EF falls within the base. But if a weight, as ABGH, is laid upon the top of the body, the centre of gravity of the whole body and weight together is raised to L; and then, as the line of direction LD falls without the base at D, the centre of gravity is not supported, and the whole body and weight will tumble down together.

Hence appears the absurdity of people's rising hastily in a coach or boat, when it is likely to overset; for by that means they raise the centre of gravity so far as to endanger throwing it quite out of the base, and if they do, they overset the vehicle effectually. Whereas, had they clapped down to the bottom, they would have brought the line of direction, and consequently the centre of gravity, farther within the base, and by that means might have saved themselves.

The broader the base, and the nearer the line of direction is to the middle or centre of it, the more firmly does the body stand. On the contrary, the narrower the base, and the nearer the line of direction is to the side of it, the more easily may the body be overthrown, a less change of position being sufficient to remove the line of direction out of the base in the latter case than in the former. And hence it is, that a sphere is so easily rolled upon a horizontal plane; and that it is so difficult, if not impossible, to make things which are sharp pointed to stand upright on the point.

From what has been said, it plainly appears, that if a plane CD on which a heavy body is placed, was elevated at C, the body would slide down upon the plane, whilst the line of direction falls within the base; but it would tumble or roll down when that line falls without the base. Thus the body E (fig. 167) would only slide down, whilst the body B would roll down upon it.

When the line of direction falls within the base of our feet, we stand, and most firmly when it is in the middle; but when it is out of that base, we immediately fall. And it is not only pleasing, but even surprising, to reflect upon the various methods and postures which we use, to retain this position, or to recover it when lost, without our being sensible of it. Thus we bend our bodies when we rise from a chair, or when we go up stairs; and for this purpose a man leans forward when he carries a burden upon his back, and backward when he carries it on his breast, and to the right or left side as he carries it on the opposite side.

If a body is suspended freely from different centres, its centre of gravity will be in the intersection formed by lines drawn from those centres perpendicular to the horizon. Hence we obtain an easy practical method of finding the centre of gravity of any irregular plane figure. Suspend it by any point, with the plane perpendicular to the horizon, and from the point of suspension hang a plumb line, and draw a line upon the body where the string passes over; do the same for any other point of suspension, and where the two lines meet must be the centre of gravity; for the centre of gravity being in each line, it must be at the point where they intersect.

MOTION, *spontaneous* or *muscular*, is that performed by the muscles at the command of the will.

MOTION, *natural* or *involuntary*, that effected, without any such command, by the mere mechanism of the parts, such as the motion of the heart, pulse, &c.

MOTION, *intestine*, the agitation of the particles of which a body consists.

MOTION, in music, the manner of beating the measure, to hasten or slacken the time of the words or notes.

MOVEMENT, in mechanics, a machine that is moved by clockwork. See CLOCK-WORK.

MOULDINGS. See ARCHITECTURE.

MOUNTAINS. Elevations consisting chiefly of clay, sand, or gravel, are called hills. Those which consist chiefly of stone are called mountains. Mountains are divided into primæval, that is, of equal date with the formation of the globe, and secondary or alluvial. Among primæval, those of granite hold the first place. The highest mountains and most extensives ridges throughout the globe are of that kind; as the Alps and Pyrenees in Europe; the Altuischan, Uralian, and Caucasus, in Asia; and the Andes, in America. The highest of them never contain metallic ores; but some of the lower contain ores of copper and tin. The granite next the ore always abounds in mica. Petrifactions are never found in these primæval mountains.

That the formation of these mountains preceded that of vegetables and animals, is justly inferred from their containing no organic remains, either in the form of petrefaction or impression. Naturalists are agreed, that granites were formed by crystallization. This operation probably took place after the formation of the atmosphere, and the gradual excavation of the bed of the ocean, when the dry land appeared. For, by means of the separation of the aëriform fluids which constitute the atmosphere, the evaporation of part of the water into the atmosphere, and the gradual retreat of the remainder, the various species of earths, before dissolved or diffused through this mighty mass, were disposed to coalesce; and among these the siliceous must have been the first, as it is the least soluble; but as the siliceous earth has an affinity to the other earths with which it was mixed, some of these must have united in various proportions, and thus have formed, in distinct masses, the feldtspar, schorl, and mica, which compose the granite. Calcareous earth enters very sparingly into the composition of this stone; but as it is found in schorl, which is frequently a component part of granite, it follows that it must be one of the primitive earths, and not entirely derived from marine exuviæ, as some have supposed. Quartz can never be supposed to be a product of fire; for in a very low heat it bursts, cracks, and loses its transparency, and in the highest degree of heat that we can produce, is infusible, so that in every essential point it is different from glass, to which some have compared it. As granite contains earths of every genus, we may conclude, that all the simple earths are original. This, however, is no proof that they are in reality simple and uncompounded of other principles; but they must be considered as such in the present state of our knowledge. Though water undoubtedly dates from creation, yet late experiments have shewn it to be a compound, as was formerly stated.

Mountains which consist of limestone or marbles of a granular or scaly texture, and not disposed in strata, seem also to have preceded the creation of animals, for no organic traces are found in them. Some of those which consist of argillaceous stones, and some of the siliceous, contain also no organic remains. These often consist of parallel strata of unequal thickness; and the lower are harder and less thick than the upper, and therefore seem to have been formed earlier than the upper.

Alluvial mountains are evidently of posterior formation, as they contain petrifactions and other vestiges of organic substances, and these are always stratified.

Mountains, as to structure, are entire, stratified, and confused. Entire mountains are formed of huge masses of stone, without any regular fissures, and are mostly homogeneous. They consist chiefly of granite, sometimes gneiss, schistus, flag-stone, sand-stone, limestone, gypsum, porphyry, or trap. Some in Sweden and Norway consist of iron ore.

The stratified mountains are those whose mass is regularly divided by joints or fissures: these are called horizontal, rising, or dipping. Homogenous stratified mountains consist chiefly of stones of the argillaceous genus, or of the fissile compound species of the siliceous genus, as metallic rock; sometimes of limestone of a granular or scaly texture, in which no animal vestiges appear. This limestone reposes on the argillaceous or siliceous strata: sometimes the argillaceous are covered with masses of granite, sometimes of lava. These mountains, particularly those of gneiss, metallic rock, and horn-stone, are the chief seat of metallic ores. When covered with limestone, the ore is generally between the limestone and the argillaceous stones. These ores run in veins, not in strata. Petrifactions are found upon, but not in, these mountains.

Heterogeneous, or compound stratified mountains, consist of alternate strata of various species of stones, earths, sands, &c. The limestone here is always of the laminar, and not of the granular or scaly, kind; and when it contains any ore, it is placed between its laminæ. Stones of the siliceous genus seldom form strata in these mountains, except lavas; but the strata are frequently interrupted by siliceous masses, as jasper, porphyry, &c. Coal, bitumen, petrifactions, and organic impressions, are found in these mountains; also salts and calamine.

There are other mountains, which cannot properly be called stratified, as they consist only of three immense masses, the lowest granite, the middle argillaceous, and the upper limestone. Metallic ores are found in the argillaceous part, or between it and the limestone.

Confused mountains consist of stones heaped together without order, their interstices filled with clay, sand, and mica. They scarcely ever contain any ore.

Besides these, there are many mountains in different parts of the world, which derive their origin from volcanoes; but of these it will be necessary to treat in a succeeding article.

The height of mountains is usually calculated by means of the barometer. For this purpose two columns of mercury, or barometers, are provided, and one is kept at the foot of the mountain while the other is carried to its summit. The degree of heat, if not equal, is reduced by calculation to an equality, and for this purpose a thermometer is attached to each of the barometers. The degree of heat to which both are reduced, is 55°. if, however, either of the barometers stands at 30 inches, and the annexed thermometer at 55°, no reduction is to be made in the degrees indicated by that barometer; but if either of them is at 30°, and the thermometer below 55°, we must add the expansion the mercury in the barometer would have experienced at the heat of 55°. If the heat should, on the contrary, be above 55°, we must abstract the degree of expansion which it gains by that heat. Every degree of Fahrenheit's scale produces an expansion of 00.304 of the barometrical inch, when the barometer is at 30; when, therefore, the thermometer is at 11° below or above 55°, we must add in the former, or subtract in the latter case, eleven times that number from the barometrical height. In the same manner it may be calculated, whatever is the height of the barometer. When this matter is ascertained, the height is easily found by comparing the two barometers, and calculating the density of the air in the higher regions according to the principles of geometrical progression.

The highest mountains are those which are situated at or near the equator; and the Andes are generally allowed to be the highest of these. Catopaxi, one of the Andes, which was measured by Ulloa and the French academicians, was found to be some miles above the level of the sea; whereas the highest point of the Alps is not above a mile and a half. Mount Caucasus approaches nearest to the height of the Andes, of any of the Asiatic mountains. The Peak of Teneriff, which has been so much celebrated, is about a mile and a half in height. It is an extraordinary circumstance, that the moon, which is a body so much smaller than our earth, should have been thought to exceed it in the irregularities of its surface; some of the mountains in that planet being formerly supposed to exceed nine miles in height: but Dr. Herschel has proved that the highest of them is not equal to one mile.

The line of congelation, or of perpetual frost, on mountains, is calculated at 15,400 feet, at or near the equator; at the entrance of the temperate zone, at 13,428; on Teneriff, at 1,000; in Auvergne (lat. 45) 6,740; with us (lat. 52) 5,740. On the Andes, vegetation ceases at 14,697 feet; and on the Alps, at 9,585. The air is so dry in these elevated situations, that M. d'Arcet observed, that on the Pic de Midi, one of the Pyrenees, salt of tartar remained dry for an hour and a half, though it immediately moistened in the same temperature at the bottom of the mountain.

MOUNTING, in military affairs, signifies going upon duty. Thus, mounting a breach, is running up to it; mounting the guard, is going upon guard; and mounting the trenches, is going upon duty in the trenches; but mounting a cannon, mortar, &c. is the setting it on its carriage, or the raising its mouth.

MOUSE. See Mus.

MOUTH. See Anatomy.

MUCILAGE, a glutinous matter obtained from vegetables, transparent and tasteless, soluble in water, but not in spirit of wine. It chiefly consists of carbon, hydrogen, and a small quantity of oxygen. See Gluten.

MUCILAGINOUS GLANDS. See Anatomy.

MUCOR, in botany, a genus of the order of fungi, in the cryptogamia class of plants. The fungus has vesicular heads supported by footstalks. There are 17 British species: the most remarkable of which are: 1. The sphærocephalus, or grey round-headed mucor, growing upon rotten wood, and sometimes upon decayed plants and mosses. The stalks of this are generally black, about a line in height, bearing each at the top a spherical ball about the size of a pin's head; its coat or rind is covered with a grey powder, and containing within a black or fuscous spongy down. The coat bursts with a ragged, irregular margin. 2. The lichenoides, or little, black, pin-headed mucor. This species grows in groups near to each other, in chasms of the barks of old trees, and upon old park-pales. The stalks are black, about two lines in height, bearing each a single head, sometimes a double or treble one, of the size of mustard or poppy seeds, of a roundish figure at first, but when burst, often flattish or truncated, and of a black colour. The internal powdered down is black, with a tinge of green. 3. The mucedo, or common grey mould, grows on bread, fruits, plants, and other substances, in a putrid state. It grows in clusters; the stalks a quarter of an inch high, pellucid, hollow, and cylindrical; supporting each a single globular head, at first transparent, afterwards dark-grey; which bursts with elastic force, and ejects small round seeds discoverable by the microscope. 4. The glaucus, or grey cluster-headed mould, is found on rotten apples, melons, and other fruits; as also upon decayed wood, and the stalks of wheat. These are of a pellucid grey colour; the stalks are generally single, supporting a spherical ball, which, when magnified, appears to be compounded of numerous, fine, moniliform, necklace-like radii. 5. The crustaceus, or fingered mould, is frequent upon corrupted food of various kinds. It is of a white aqueous colour; the stalks single, each supporting at the top four or five necklace-like radii, diverging from the same point or centre. 6. The septicus, or yellow frothy mucor, is found on the leaves of plants, such as ivy and beech, &c. sometimes upon dry sticks, and frequently upon the tan or bark in hot-houses. It is of no certain size or figure, but of a fine yellow colour, and a substance resembling at first cream beaten up into froth. In the space of 24 hours it acquires a thin filmy coat, becomes dry, and full of a sooty powder adhering to downy threads. The seeds under the microscope appear to be globular. Haller ranks it under a new genus, which he terms fuligo; the characters of which are, that the plants contained under it are soft, and like butter at first, but soon change into a black sooty powder.

MUCOUS ACID. See Salactic acid.

Mucous gland. See Anatomy.

MUCUS, a fluid secreted by certain glands, and serving to lubricate many of the internal cavities of the body. In its natural state it is generally limpid and colourless; but from certain causes, will often assume a thick consistence and whitish colour like pus. As it is sometimes of very great importance in medicine to distinguish these two fluids from each other, this was lately proposed as the subject of a prize disputation by the Æsculapian Society of Edinburgh. The prize was gained by Mr. Charles Darwin, student of medicine from Litchfield.

The conclusions drawn from his experiments were, 1. Pus and mucus are both soluble in the vitriolic acid, though in very different proportions, pus being by far least soluble. 2. The addition of water to either of these compounds decomposes it. The mucus thus separated either swims in the mixture, or forms large flocculi in it; whereas the pus falls to the bottom, and forms, on agitation, an uniform turbid mixture. 3. Pus is diffusible through a diluted vitriolic acid, though mucus is not. The same also occurs with water, or with a solution of sea-salt. 4. Nitrous acid dissolves both pus and mucus. Water added to the solution of pus produces a precipitate, and the fluid above becomes clear and green, while water and the solution of mucus form a turbid dirty-coloured fluid. 5. Alkaline lixivium dissolves, though sometimes with difficulty, mucus, and generally pus. 6. Water precipitates pus from such a mixture, but does not mucus. 7. Where alkaline lixivium does not dissolve pus, it still distinguishes it from mucus, as it then prevents its diffusion through water. 8. Coagulable lymph is neither soluble in concentrated nor diluted vitriolic acid. 9. Water produces no change on a solution of serum in alkaline lixivium, until after long standing, and then only a very slight sediment appears. 10. Corrosive sublimate coagulates mucus, but does not pus.

From the above experiments, it appears that strong sulphuric acid and water, diluted sulphuric acid, and caustic alkaline lixivium and water, will serve to distinguish pus from mucus; that the vitriolic acid can separate it from coagulable lymph, and alkaline lixivium from serum. Hence, when a person has any expectorated matter, the decomposition of which he wishes to ascertain, let him dissolve it in vitriolic acid, and in caustic alkaline lixivium; and let him add pure water to both solutions. If there is a fair precipitation in each, he may be assured that some pus is present. But if there is a precipitation in neither, it is a certain test that the mixture is entirely mucus. If the matter cannot be made to dissolve in alkaline lixivium by time and trituration, we have also reason to believe that it is pus.

Mucus, nasal: this name is given to a liquid which is secreted in the cavities of the nose, and is discharged outwardly, either by the nostrils in the form of drops, or in that of masses more or less thick; or by the fauces when it descends by the posterior part of the nasal cavities, in which it is thrown out by spitting. This liquid is separated from the blood by the arteries, and appears to be formed in particular crypts, which we find abundantly disseminated in the nostrils: it is collected also from all the frontal sinuses. It is also mixed with the lachrymal juice, which descends by the channel which passes through the os unguis, and dilutes the thickened nasal mucus.

We must particularly consider both the abundance and the characters of this liquid in the catarrh, improperly called catarrh of the brain, in which the nasal mucus is separated in larger quantity, and remains a longer time in its ducts. "It is," says M. Fourcroy, "especially under this circumstance, that citizen Vauquelin and myself have examined it, as we then procured it with great facility. We have also availed ourselves of the considerable discharge of mucus which is produced by the contact of the oxigenated muriatic acid gas, in order to obtain a sufficient quantity of it for the experiments adapted for making us well acquainted with its nature. It has several times happened to citizen Vauquelin, who is very sensible to the action of the oxigenated muriatic acid gas, that he has collected by its effect 64 grammes of this liquid in less than an hour. By means of these circumstances we have been enabled to determine its nature in a considerably exact manner. It is known that this liquid is very abundant in children, that it is a little heavier than water, and adheres to most bodies, even the most polished."

The nasal mucus is at first liquid, clear and limpid, a little viscid and adhesive, without smell, of a saline and acrid taste, which irritates the most delicate part of the skin; it is then really the pituita vitrea of the antients. When exposed to the air and to the fire, it comports itself in the same manner as the tears, from which it differs only by the abundance of its residuum, which is thicker, and frequently more coloured. It affords crystals of muriate of soda, of soda in the state of carbonate, and of phosphates of lime and of soda; the last are much more abundant than the others. It turns paper stained with mallow-flowers green, by its salts: we also find in it an animal matter which is not albuminous, but quickly becomes thick and concrete by the oxigen of the air and of the oxigenated muriatic acid; it then acquires opacity, and a yellow or greenish colour, swells considerably, and becomes filled with bubbles by the action of fire, leaving but little residuum upon the ignited coals. This animal mucilage, which is more abundant than in the tears, appears to be of the same nature in both.

This liquid, being always exposed to the air, which continually passes through the nostrils, is constantly thicker, more viscid, and more adhesive, than the tears; and the carbonate of soda which it contains, whilst the latter contains only soda, announces that the air deposits in it a part of the carbonic acid which it contains, especially as it is expired out of the lungs. Consequently, it then renders the solutions of barytes, of strontian, and of lime, very sensibly turbid. In the nostrils, the heat of the plant, especially in catarrhs, and the current which incessantly acts upon it, contribute also to thicken it. The mucilage of the nasal humour, when it becomes thick in the air, frequently assumes in it the form of small, dry, brilliant, and, as it were, micaceous plates. If it has dried in very thin layers, it nearly resembles those brilliant and light marks which snails leave behind them upon the substances over which they crawl. The nasal mucus experiences no real putrefaction in the air; we should almost be induced to say that it was unalterable and imputrescible, when we see it remain without contracting any bad smell, even in the midst of water, and at a considerably elevated temperature. However, this property of preservation does not extend so far as to communicate itself to other bodies that are immersed in it.

Water does not dissolve the mucus of the nose. It is known that this matter remains viscid in that fluid, and that it cannot be diluted in water without much difficulty, even by agitation. Hot water and ebullition do not render this singular mixture more miscible or more soluble. In boiling water, it appears at first to form one body with the water; nevertheless, we see it separate and fall to the bottom of this liquid by cooling. It is probable that this insolubility is owing to the fixation of the oxigen. Neither has it the property of rendering oils miscible with water, nor of effecting their suspension by trituration, as a vegetable mucilage does. It is on this account that when we wash, or even boil, this thick humour in water, the salts which it contains are dissolved and separated, without affecting the mucilage which constitutes its base.

The acids thicken the nasal mucus when they are concentrated and employed in small proportions; but when we add a larger quantity, they redissolve and give it different shades of colour. The sulphuric acid tinges it purple, and renders it very liquid, forming however some flakes in it which sink to the bottom. The nitric acid, when rather strong, dissolves it of a yellow colour. The muriatic acid is that which effects its solution the most easily and the most completely of all, giving it a violet-colour. The alkaline, or earthy salts, do not cause it to undergo any alteration, nor do they dissolve it.

The mucus of the nostrils being especially distinguished from all the other animal liquids by the viscid mucilage which it contains in considerable abundance, it is evidently from the presence of this principle that we ought to seek its uses, and the function which it performs in the animal economy. Besides the kind of evacuation, sometimes very abundant, which it procures; and the proportion of the evacuated matter compared with that of the other excretory organs, which it carries out of the body; this liquid maintains the softness of the membranous sides of the nasal cavities, and prevents that dryness which the air passing in continual streams through these cavities tends to produce in them. It moderates the too great sensibility of the nervous papillæ which are spread out upon the olfactory membrane; it stops and fixes the odorous bodies, it blunts their too great activity; it purifies the air that is respired, by taking from it the pulverulent particles which it carries along with it, and which would be more hurtful in the lungs. Being always contained in a hot, humid, and arid place, three circumstances which would so eminently promote putrefaction, provident nature has given it a property which opposes the septicity which would have exposed man and the animals to a multitude of dangerous vitiations and maladies.

It is known that the mucus of the nostrils is capable of changing its nature, and assuming various properties, in the nasal affections. It thickens, becomes yellow, orange-coloured, or greenish, frequently tinges linen with a very lively green cast by drying upon it; it sometimes produces the sensation of the presence of copper; and sometimes it exhales a nauseous or fetid smell. In some affections it becomes so acrid that it seems to corrode the membrane of the nostrils, and produces excoriations round their orifices, as well as upon the upper lip. Lastly, it is sometimes liquid like water, at others ropy like oil: in several cases thick, viscid, and always transparent, like jelly; in other circumstances, semiconcrete, and white, yellow, or green, like a purulent humour. None of these changes have yet been chemically examined, and hardly even has the attention which they deserve been bestowed upon them.

MUFTI, or MUPHTI, the chief of the ecclesiastical order, or primate, of the mussulman religion. The authority of the mufti is very great in the Ottoman empire; for even the sultan himself, if he would preserve any appearance of religion, cannot, without hearing his opinion, put any person to death, or so much as inflict any corporal punishment. In all actions, especially criminal ones, his opinion is required by giving him a writing, in which the case is stated under feigned names, which he subscribes with the words, *He shall*, or *shall not, be punished*. Such outward honour is paid to the mufti, that the grand seignior himself rises up to him, and advances seven steps to meet him, when he comes into his presence. The election of the mufti is solely in the grand seignior, who presents him with a vest of rich sables, &c. If he is convicted of treason, or any great crime, he is put into a mortar, kept for that purpose in the Seven Towers at Constantinople, and pounded to death.

MUGGLETONIANS, a religious sect, which arose in England about the year 1657; so denominated from their leader Lodowick Muggleton, a journeyman taylor, who, with his associate Reeves, asserted, that they were the two last witnesses of God that should appear before the end of the world.

MUGIL, *mullet*, a genus of fishes of the order abdominales. The generic character is, lips membranaceous; the inferior carinated within: teeth none; at the corners of the mouth an inflicted callus: gill-membrane with six curved rays: body fleshy; scales large; dorsal fins two.

1. Mugil cephalus, common mullet. This fish, the mugil and mugilis of the antient Romans, is a very common inhabitant of the Mediterranean and northern seas, frequenting chiefly the shallow parts near the shores, and feeding on the smaller kind of worms, sea-insects, and vegetables. Its general length is from 12 to 15 or 16 inches, and its colour blueish-grey, darker on the back, and silvery on the abdomen; the sides are marked, like those of the grayling, with several dusky stripes, according to the rows of scales,

which are large and rounded; the fins are blueish; the first dorsal fin, which is situated on the middle of the back, consists of four very strong rays; the second dorsal fin is placed opposite the anal, and has only soft rays; the base of the dorsal and anal fin, as well as that of the tail, is scaly, and the tail is forked or lunated.

The mullet is found not only in the European seas, but in the Indian and Atlantic oceans. It is observed to assemble frequently in small shoals near the shore, in quest of food, burrowing into the soft mud, and leaving the trace of its head in the form of a round hole.

In the spring and early summer months, this fish, like the salmon, ascends rivers to a considerable distance; and when preparing for these expeditions, is observed in shoals near the surface of the water, at which time the fishermen endeavour to avail themselves of the opportunity of surrounding them with their nets, which the fish are said to shew great address in escaping from.

The mullet is considered as an excellent fish for the table, though not a fashionable one in our own country. Dr. Bloch informs us, that it is generally eaten with the addition of oil and lemon-juice. The spawn is often prepared into an inferior kind of caviar, called botargo, by drying and salting it; in which manner also the fish itself, in plentiful seasons, is occasionally preserved. See Plate Nat. Hist. *fig.* 272.

2. Mugil crenilabis, crenated mullet. Size of the common mullet; length about twelve inches; colour whitish; scales rather large, and marked by a dusky streak; upper lip gaping, lower bicarinated within, and both lips crenulated on the edges; fins glaucous white, the pectoral marked at the base by a round black spot; tail forked: native of the Red Sea. There are seven other species.

MUG-WORT, in botany. See ARTEMESIA.

MUHLENBERGIA, a genus of the class and order triandria digynia. The calyx is one-leaved, minute, lateral; corolla two-valved. There is one species, a grass of America.

MUID, a large measure in use among the French, for things dry. The muid is no real vessel used as a measure, but an estimation of several other measures, as the septier, mine, minot, bushel, &c.

MUID is also one of the nine casks, or regular vessels, used in France, to put wine and other liquors in. The muid of wine is divided into two demi-muids, four quarter-muids, and eight half-quarter muids, containing 36 septiers.

MULBERRY See MORUS.

MULE, in zoology, a mongrel kind of quadruped, usually generated between an ass and a mare, and sometimes between a horse and a she-ass; but the signification of the word is commonly extended to every kind of animal produced by a mixture of two different species. There are two kinds of these animals: one from the he-ass and mare, the other from the horse and the she-ass. We call them indifferently mules, but the Romans distinguished them by proper appellations. The first kind are the best and most esteemed, as being larger, stronger, and having least of the ass in their disposition. The largest and stoutest asses, and the fairest and finest mares, are chosen in those countries where these creatures are most in use; as in Spain, Italy, and Flanders. In the last especially, they succeed in having very stately mules from the size of their mares, some of them 16 and some 17 hands high, which are very serviceable as sumpter-mules in the army. But since the Low-countries are no longer under the dominion of Spain, they breed fewer mules. These creatures are very much commended for their being stronger, surer-footed, going easier, being more cheaply maintained, and lasting longer, than horses. They are commonly of a black brown, or quite black, with that shining list along the back and cross the shoulders which distinguishes asses. In former times they were much more common in this country than at present, being often brought over in the days of popery by the Italian princes. They continued longest in the service of millers, and are yet in use among them in some places, on account of the great loads they carry on their back. As they are capable of being trained for riding, bearing burdens, and for draught, there is no doubt that they might be usefully employed in many different services. But they are commonly found to be vicious, stubborn, and obstinate to a proverb; which whether it occasions or is produced by the ill usage they meet with, is a point not easily settled. Whatever may be the case of asses, it is allowed that mules are larger, fairer, and more serviceable, in mild than in warm climates. In the British American colonies, both on the continent and in the islands, but especially in the latter, they are much used and esteemed; so that they are frequently sent to them from hence; suffer less in the passage, and die much seldomer, than horses; and commonly yield, when they arrive, no inconsiderable profit.

It has commonly been asserted, that animals produced by the mixture of two heterogeneous species, are incapable of generating, and thus perpetuating the monstrous breed: but this, we are informed by M. Buffon, is now discovered to be a mistake.

MULES, among gardeners, denote a sort of vegetable monsters produced by putting the farina fecundans of one species of plant into the pistil or utricle of another. The carnation and sweet-william being somewhat alike in their parts, particularly their flowers, the farina of the one will impregnate the other, and the seed so enlivened will produce a plant differing from either. An instance of this we first had in Mr. Fairchild's garden at Hoxton, where a plant is seen neither sweet-william nor carnation, but resembling both equally: this was raised from the seed of a carnation that had been impregnated by the farina of the sweet-william. These couplings being not unlike those of the mare with the ass, which produce the mule, the same name is given them; and they are, like the others, incapable of multiplying their species. This furnishes a hint for altering the property and taste of any fruit, by impregnating one tree with the farina of another of the same class, *e. g.* a codlin with a pearmain, which will occasion the codlin so impregnated to last a longer time than usual, and to be of a sharper taste. Or if the winter fruits are fecundated with the dust of the summer kinds, they will ripen before their usual time. And from this accidental coupling of the farina of one with another, it may possibly be, that in an orchard where there is variety of apples, even the fruit gathered from the same tree differ in their flavour, and in the season of maturity. It is also from the same accidental coupling that the numberless varieties of fruits and flowers raised every day from seed proceed.

MULLER, or MULLAR, denotes a stone flat and even at the bottom, but round at top, used for grinding of matters on a marble. The apothecaries use mullers to prepare some of their testaceous powders; and painters for their colours, either dry or in oil.

MULLERIA, a genus of the class and order diadelphia decandria. The pericarp is elongated, fleshy, necklace-form, with one-seeded globules. There is one species, a tree of Surinam.

MULLET, or MOLLET, in heraldry, a bearing in form of a flat, or rather of the rowel of a spur, which it originally represented.

MULLUS, *surmullet*, a genus of fishes of the order thoracici. The generic character is, head compressed, scaly; mouth bearded; gill-membrane three-rayed; body covered with large subdeciduous scales.

1. Mullus ruber, the red surmullet, is principally found in the Mediterranean and northern seas, where it arrives at the length of 12 or 15 inches: its colour is an elegant rose-red, tinged with olive-colour on the back, and of a silvery cast towards the abdomen. The surmullet is a fish of a strong and active nature, swimming briskly, and feeding principally on the smaller fishes, worms, and sea-insects. It is generally considered as a very delicate fish, and is celebrated for having been the fashionable object of Roman luxury, and for which such enormous sums are reported to have been sometimes given; though it is probable that the high estimation in which it was held by the antient Greeks and Romans was more owing to a prejudice entertained on account of its elegant appearance, than to its real merit as a food. The Romans practised a singular refinement in luxury, by first bringing the fish alive to the table in a glass vessel, in order that the guests might enjoy the pleasure of contemplating the beautiful changes of its evanescent colours during the time of its gradual expiration; after which it was prepared for their repast.

2. Mullus surmuletus, striped surmullet, of similar size and general appearance with the preceding, but marked on each side by two and sometimes three longitudinal yellow stripes: native of the Mediterranean, but found occasionally in the Atlantic and other seas: in equal esteem as a food with the former, of which it has even been considered by some authors as a variety.

3. Mullus Indicus, Indian surmullet. Size and habit of the common or red mullet; colour extremely beautiful in the living fish, but fading very soon after death; upper part of the head and back dark changeable purple, growing faint on the sides, which are marked by a few longitudinal azure and golden lines, and by two oblong spots on each side; the first situated about the middle of the body, smallish, and of an opaline or changeable golden and white colour; the second situated near the tail, larger, and of a dark purple; abdomen white; dorsal fin

purple, streaked with light blue; pectoral and anal pink-colour: native of the Indian seas: observed by Dr. Russel near Visgapatam: inferior as a food to the red mullet, and not much esteemed.

4. Mullus barbatus, inhabits the European, Mediterranean, and Pacific seas: body, when deprived of its scales, red. Nothing can be more beautiful than the colours of this fish, when in the act of dying; and nothing more delicious than its flesh. The Romans held it in such repute, that prodigious sums were given for them: they were frequently bought at their weight in pure silver. See Plate Nat. Hist. fig. 273. There are two other species.

MULTILATERAL, in geometry, is applied to those figures which have more than four sides or angles, more usually called polygons.

MULTINOMIAL, or MULTINOMIAL ROOTS, in mathematics, such roots as are composed of many names, parts, or members; as, $a + b + d + c$, &c. See ROOT.

MULTIPLE, in arithmetic, a number which comprehends some other several times, thus 6 is a multiple of 2.

MULTIPLE RATIO, OR PROPORTION, is that which is between multiples. If the less term of the ratio is an aliquot part of the greater, the ratio of the greater to the less is called multiple, and that of the less to the greater submultiple. A submultiple number is that contained in the multiple; thus, the numbers 1, 2, and 3, are submultiples of 9. Duple, triple, &c. ratios, as also subduples, subtriples, &c. are so many species of multiple and submultiple ratios. See RATIO.

MULTIPLICAND. See ARITHMETIC.

MULTIPLICATION. See ARITHMETIC, and ALGEBRA.

MULTIPLYING GLASS. See OPTICS.

MUM, a kind of malt liquor, much drunk in Germany, and chiefly brought from Brunswick, which is the place of most note for making it.

MUMMY. See EMBALMING.

MUNCHAUSIA, a genus of the class and order polyadelphia polyandria. The calyx is six-cleft; petals clawed; stamina in six bodies; pistils superior. There is one species, a tree of Java.

MUNICIPAL, in the Roman civil law, an epithet which signifies invested with the rights and privileges of Roman citizens. Thus the municipal cities were those whose inhabitants were capable of enjoying civil offices in the city of Rome.

Municipal, among us, is applied to the laws that obtain in any particular city or province: and those are called municipal officers who are elected to defend the interest of cities, to maintain their rights and privileges, and to preserve order and harmony among the citizens; such as mayors, sheriffs, &c.

MUNTINGIA, a genus of the class and order polyandria monogynia. The calyx is five-parted; corolla five-petalled; berry five-celled; seeds many. There is one species, a shrub of Jamaica.

MURÆNA, a genus of fishes of the order apodal. The generic character is, body eel-shaped; pectoral fins none; spiracle on each side the neck.

1. Muræna Helena, Roman muræna. This fish, the celebrated favourite of the antient Romans, who considered it as one of the most luxurious articles of the table, is found in considerable plenty about several of the Mediterranean coasts, where it arrives at a size at least equal, if not superior, to that of an eel. Its colour is a dusky greenish-brown, pretty thickly variegated on all parts with dull-yellow subangular marks or patches, which are disposed in a somewhat different manner in different individuals, and are generally scattered over with smaller specklings of brown, the whole forming a kind of obscurely reticular pattern. The muræna is capable of living with equal facility both in fresh and salt water, though principally found at sea. In its manners, it much resembles the eel and the conger, being extremely voracious, and preying on a variety of smaller animals. The antients, who kept it in reservoirs appropriated for the purpose, are said to have sometimes tamed it to such a degree as to come at the signal of its master in order to receive its food. Pliny records a most disgusting and barbarous instance of tyranny practised by one Vedius Pollio, who was in the habit of causing his offending slaves to be thrown into the reservoirs in which he kept his murænæ; expressing a savage delight in thus being able to taste in an improved state their altered remains. The emperor Augustus, according to Seneca, honoured this man with his presence at one of his entertainments; when a slave happening to break a valuable chrystal vase, was immediately ordered to be thrown to the murænæ; but the poor boy, flying to the feet of Augustus, requested rather to die any death than thus to be made the food of fishes. The emperor, being informed of this extraordinary mode of punishment, immediately ordered all the chrystal vessels in the house to be broken before his face, and the ponds of the barbarous owner to be completely filled up; at the same time giving the slave his freedom, but sparing the life of the offender in consideration of former friendship. See Plate Nat. Hist. fig. 276.

2. Muræna ophis, spotted muræna. Observed by Forskal; native of the Red Sea; has a rising callus between the eyes, gold-coloured irides, upper lip shorter than the lower, and the dorsal and anal fins united at the tail. See Plate Nat. Hist. fig. 275.

3. Muræna catenata, chain-striped muræna. This species, of which the individuals hitherto described appear to be of the size of a smallish eel, is of a brown colour, crossed by large chainlike white bands, somewhat irregular in their form on different parts of the animal, and marked by numerous brown spots and freckles. This fish is a native of Surinam.

4. Muræna reticulata, reticulated muræna. In size and general form, this resembles the preceding species, but differs in colours and in the disposition of the dorsal fin, which commences immediately at the back of the head, and is continued round the tail, where it unites with the vent-fin. Native of the Indian seas.

5. Muræna conger, conger eel; inhabits the European seas and rivers; is extremely voracious, feeding on other fish, crabs in their soft state, and particularly carcases. It grows to a vast size. See Plate Nat. Hist. fig. 274. There are four other species.

MURDER, or MURTHER. See HOMICIDE.

MUREX, in natural history, a genus of univalve or simple shells, without any hinge, formed of a single piece, and beset with tubercles or spines. The mouth is large and oblong, and has an expanded lip, and the clavicle is rough.

The clavicle of the murex is in some species elevated, in others depressed; and the mouth is sometimes dentated, and at others smooth; the lip also in some is digitated, in others elated, and in some laciniated; and the columella is in some smooth, in others rugose.

MUREX, in zoology, a genus of insects belonging to the order of vermes testacea. This animal is of the snail kind: the shell consists of one spiral valve, rough, with membranaceous furrows; and the aperture terminates in an entire canal, either straight, or somewhat ascending. There are 60 species, particularly distinguished by peculiarities in their shells, &c. See Plate Nat. Hist. figs. 277, 278.

In the accounts of a Spanish philosopher it is mentioned, that on the coasts of Guayaquil and Guatimala in Peru, the murex is also found. The shell which contains it adheres to the rocks that are washed by the sea. It is of the size of a large walnut. The liquor may be extracted two ways: some kill the animal after they have drawn it out of the shell, then press it with a knife from head to tail, separate from the body the part where the liquor is collected, and throw away the rest. When this operation, after being repeated on several snails, has afforded a certain quantity of fluid, the thread intended to be dyed is dipped in it, and the process is finished. The colour, which is at first of the whiteness of milk, becomes afterwards green, and is not purple till the thread is dry. Those who disapprove of this method draw the fish partly out of the shell, and, squeezing it, make it yield a fluid which serves for dyeing: they repeat this operation four times at different intervals, but always with less success. If they continue it, the fish dies. No colour at present known, says the Abbé Raynal, can be compared to this, either as to lustre, liveliness, or duration. It succeeds better on cotton than wool, linen, or silk.

MURIAT, *green sand of Peru.* This ore, which was brought from Peru by Dombey, is a grass-green powder, mixed with grains of quartz. When thrown on burning coals, it communicates a green colour to the flame. It is soluble both in nitric and muriatic acids without effervescence. The solution is green. This mineral was first proved to contain muriatic acid by Berthollet. Afterwards Proust analyzed it. But Vauquelin announced that he considered it merely as an oxide of copper mixed with common salt. However, a subsequent examination convinced him that his opinion was unfounded; and that the mineral was really a carbonat, as had been affirmed by Berthollet and Proust. This conclusion has been confirmed by Klaproth, who found the green sand of Peru composed of

73.0	oxide of copper
10.1	muriatic acid
16.9	water.
100.0	

MURIATIC ACID. This substance may be procured by the following process: Let a small pneumatic trough be procured, hollowed out of a single block of wood, about 14 inches long, seven broad, and six deep. After it has been hollowed out to the depth of an inch, leave three inches by way of shelf on one side, and cut out the rest to the proper depth, giving the inside of the bottom a circular form. Two inches from each end cut a slit in the shelf to the depth of an inch, and broad enough to admit the end of small glass tubes, or the points of small retorts. This trough is to be filled with mercury to the height of one quarter of an inch above the surface of the shelf. Small glass jars are to be procured of considerable thickness and strength, and suitable to the size of the trough. One of them, being filled with mercury by plunging it into the trough, is to be placed on the shelf over one of the slits. It ought to be supported in its position; and the most convenient method of doing that is to have a brass cylinder two inches high screwed into the edge of the trough, just opposite to the border of the shelf. On the top of it are fixed two flat pieces of brass, terminating each in a semicircle, moveable freely upon the brass cylinder, and forming together a brass arm terminating in a circle, the centre of which is just above the middle of the slit in the shelf, when turned so as to be parallel to the edge of the shelf. This circle is made to embrace the jar: being formed of two distinct pieces, its size may be increased or diminished at pleasure; and by means of a brass slider it is made to catch the jar firmly.

The apparatus being thus disposed, two or three ounces of common salt are to be put into a small retort, and an equal quantity of sulphuric acid added; the beak of the retort plunged below the surface of the mercury in the trough, and the heat of a lamp applied to the salt in its bosom. A violent effervescence takes place; and air-bubbles rush in great numbers from its beak, and rise to the surface of the mercury in a visible white smoke, which has a peculiar odour. After allowing a number of them to escape, till it is supposed that the common air which previously existed in the retort has been displaced, plunge its beak into the slit in the shelf over which the glass jar has been placed. The air-bubbles soon displace the mercury and fill the jar. The gas thus obtained is called muriatic acid gas.

This substance, in a state of solution in water, was known even to the alchemists; but in a gaseous state it was first examined by Dr. Priestley, in an early part of that illustrious career in which he added so much to our knowledge of gaseous bodies.

1. Muriatic acid gas is an invisible elastic fluid, resembling common air in its mechanical properties. Its specific gravity, according to the experiments of Mr. Kirwan, is 0.002315, or nearly double that of common air. Its smell is pungent and peculiar; and whenever it comes in contact with common air, it forms with it a visible white smoke. If a bottle of it is drawn into the mouth, it is found to taste excessively acid; much more so than vinegar.

2. Animals are incapable of breathing it, and when plunged into jars filled with it, they die instantaneously in convulsions. Neither will any combustible burn in it. It is remarkable, however, that it has a considerable effect upon the flame of combustible bodies; for if a burning taper is plunged into it, the flame, just before it goes out, may be observed to assume a green colour, and the same tinge appears next time the taper is lighted.

3. If a little water is let up into a jar filled with this gas, the whole gas disappears in an instant, the mercury ascends, fills the jar, and pushes the water to the very top. The reason of this is, that there exists a strong affinity between muriatic acid gas and water; and whenever they come in contact, they combine and form a liquid, or, which is the same thing, the water absorbs the gas. Hence the necessity of making experiments with this gas over mercury. In the water cistern not a particle of gas would be procured. Nay, the water of the trough would rush into the retort and fill it completely. It is this affinity between muriatic acid gas and water which occasions the white smoke that appears when the gas is mixed with common air. It absorbs the vapour of water which always exists in common air. The solution of muriatic acid gas in water is usually denominated simply muriatic acid by chemists.

4. If a little of the blue-coloured liquid which is obtained by boiling red cabbage-leaves and water, is let up into a jar filled with muriatic acid gas, the usual absorption of the gas takes place, but the liquid at the same time assumes a fine red colour. This change is considered by chemists as a characteristic property of acids.

5. Muriatic acid gas is capable of combining with oxygen. To obtain the combination, we have only to put a quantity of the black oxide of manganese in powder into a retort, and pour over it liquid muriatic acid. Heat is then to be applied to the mixture, and the beak of the retort plunged under water. An effervescence takes place, and a green-coloured gas comes out at the beak of the retort, which may be received in the usual manner in jars. This gas has been ascertained to be a compound of muriatic acid and oxygen. It is called oxy-muriatic acid, and will come under our consideration hereafter.

6. It does not appear from any experiments that have been hitherto made, that any of the simple combustibles are capable of combining with muriatic acid gas. Dr. Priestley found, that sulphur absorbed slowly about the fifth part of it. What remained was inflammable air, burning with a blue flame, and not absorbed by water. He found that phosphorus scarcely absorbed any sensible quantity of it, and that charcoal absorbed it very fast. Hydrogen gas does not produce any sensible change in it. Neither does it seem capable of being affected by azotic gas.

Muriatic acid is capable of combining with two doses of oxygen only. With the first dose, it forms oxymuriatic acid; with the second, hyperoxymuriatic acid. The first of them ought, in strict propriety, to be termed an oxide rather than an acid.

MURIATS. The muriats are a genus of salts which have been long known, and from which indeed the whole of the class have borrowed their name; for to them belongs common salt, the most important and the most indispensably necessary of all the salts. They may be distinguished by the following properties:

When heated, they melt, and are volatilized, at least in part, without undergoing decomposition. The first portions which fly off contain an excess of acid.

Not in the least altered by combustibles, even when assisted by heat.

Soluble in water. For the most part they raise the boiling-point of water.

Effervesce with sulphuric acid, and white acrid fumes of muriatic acid are disengaged.

When mixed with nitric acid, they exhale the odour of oxymuriatic acid.

MURRAIN, or Gargle, a contagious disease among cattle, principally caused by a hot dry season, or rather by a general putrefaction of the air, which begets an inflammation of the blood, and a swelling in the throat, that soon proves mortal, and is communicated from one to another, though it generally goes no farther than to those of the same kind.

The symptoms of this disease are, a hanging down and swelling of the head, abundance of gum in the eyes, rattling in the throat, a short breath, palpitation of the heart, staggering, a hot breath, and a shining tongue.

MURRAYA, a genus of the class and order decandria monygynia. The calyx is five-parted; corolla bell-shaped, with a nectarium encircling the germ; berry one-seeded. There is one species, a tree of the East Indies.

MUS, *the rat*, a genus of quadrupeds of the order glires. The generic character is, upper front-teeth wedge-shaped; grinders on each side three, sometimes only two; clavicles or collar-bones in the skeleton.

This numerous tribe constitutes a formidable phalanx against which mankind find it necessary to employ the various artifices of extirpation, in order to lessen the ravages occasionally suffered by its depredations. In our own island, the black and the brown rats, the field and domestic mice, are the principal destroyers; but in other parts of Europe, as well as in the hotter regions of Asia, Africa, and America, many other species, still more noxious and formidable, are found. The different kinds vary considerably in their manner of life, some confining themselves entirely to vegetable food, while others are polyphagous, destroying with indiscriminate avidity almost any animal or vegetable substance to which they can gain access. Their pace is, in general, rather quick, and their most usual residence is in obscure subterraneous retreats, from which they principally emerge by night. They are of a prolific nature, and the females are furnished with numerous teats. Some species are migratory; others local or attached to the same residence. Lastly, some are of an uncouth form and disagreeable appearance, while others are remarkable for the elegance of their colours. In the 12th edition of the Systema Naturæ, Linnæus included in this genus the jerboas, the cavys, and several other animals which are now formed into distinct genera. This mode of distribution might perhaps be carried still farther, the habit or appearance of some species differing very considerably from that of the major part of the tribe.

1. Mus zibethicus, musk rat. In the Memoirs of the French Academy of Sciences for the year 1725, there is a complete and excellent description of this animal by Mons. Sarrazin, at that time king's physician at Quebec. It is from the above description that the count de Buffon has drawn up the major part of his own account, and indeed it does not appear possible to add any thing material to what Mons. Sarrazin has delivered. This animal is of the size of a small rabbit, and is extremely common in Canada. Its head is short, like that of a water-rat; the eyes large; the ears very short, rounded, and covered internally as well as externally with hair. It has, like the rest of this tribe, four very strong cutting teeth, of which those in the lower jaw are near an inch long; those in the upper somewhat shorter: the fur on the whole body is soft and glossy, and beneath is a fine fur, or thick down, as in the beaver; the toes on all the feet are simple, or without membranes, and are covered with hair; the tail is nearly as long as the body, and is of the same form with that of the sorex moschatus or musk shrew, being laterally compressed; it is nearly naked, and covered with small scales intermixed with scattered hairs. The general colour of the animal is a reddish brown; of the tail ash-colour. In its general appearance this animal greatly resembles the beaver, except in size, and in the form of its tail. It has also similar instincts and dispositions; living in a social state in the winter, in curiously-constructed huts or cabins, built near the edge of some lake or river. These huts are about two feet and a half or three feet in diameter, plaistered with great neatness in the inside, and covered externally with a kind of basket-work, of rushes, &c. interlaced together so as to form a compact and secure guard, impermeable by water. During the winter these receptacles are generally covered by several feet of snow, and the animals reside in them without being incommoded by it, several families commonly inhabiting each cabin. It is added that the insides of the receptacles are furnished with a series of steps, to prevent them from being injured by inundations. These animals do not lay up a stock of provisions like the beaver, but form subterraneous passages beneath and round their cabins, to give themselves an opportunity of procuring occasional supplies of roots, herbage, &c. According to Mons. Sarrazin the animal is particularly calculated by nature for its subterraneous habits, having a great muscular force in its skin, which enables it to contract its body occasionally into a small volume: it has also a great suppleness in the false ribs, which easily admit of contraction, so that it is enabled to pass through holes impervious to much smaller animals than itself.

During the summer these creatures wander about in pairs, feeding voraciously on herbs and roots. Their odour, which resembles that of musk, is so strong as to be perceived at a considerable distance; and the skin, when taken from the body, still retains the scent: this musky odour is owing to a whitish fluid deposited in certain glands situated near the origin of the tail. It has been supposed that the calamus aromaticus, or sweet flag (acorus calamus, Lin.), which these animals select as a favourite food, may contribute to their fragrant smell. They walk and run in an awkward manner, like the beaver, and they cannot swim so readily as that animal, their feet being unfurnished with webs. Their voice is said to resemble a groan. The females produce their young towards the beginning of summer, and have five or six at a time; and these, if taken early, are easily tamed, and become very sportive; and it is remarkable that the tail, which in the full-grown animal is as long as the body, is at that period very short.

The fur of this species is greatly esteemed as a commercial article, resembling that of the beaver. Linnæus, in the twelfth edition of the Systema Naturæ, ranked the animal under the genus castor; and Mr. Pennant has followed his example. Mr. Schreber, however, considers it as belonging in strict propriety to the present genus. See Plate Nat. Hist. fig. 279.

2. Mus decumanus, Norway rat. This domestic species, which is now become the common rat of our own island, and is popularly known by the name of the Norway rat, is supposed to be a native of India and Persia, from which countries it has been imported into Europe. In England it seems to have made a national conquest over the black rat, which is now become rare in comparison. The brown rat is larger than the black rat, measuring nine inches from the nose to the tail, which is of the same length, and marked into about 200 rings or circular spaces; the colour of the animal is a pale tawny-grey, whitish beneath; the fore feet have four toes, with a claw in place of a fifth. It is a bold and voracious animal, and commits great havoc in granaries, &c. Sometimes it takes up its residence in the banks of waters, and swims occasionally with almost as much facility as the water rat, or mus amphibius. In its general manner of life it agrees with the black rat; and not only devours grain and fruits, but preys on poultry, rabbits, and various other animals. It is a very prolific species, and produces from ten to twelve or fourteen, or even sometimes eighteen, young at a time. When closely pursued, it will sometimes turn upon its adversary, and bite with great severity. It seems to have made its first appearance in England about seventy years ago, and is still much less frequent in France and some other parts of the continent than the black rat.

3. Mus rattus, black rat. This species, like the former, though now so common in most parts of Europe, is supposed to have been originally introduced from India and Persia. Its general length from nose to tail is seven inches, and of the tail eight inches; the colour of the head and whole upper part of the body is a dark iron or blackish grey; the belly is of a dull ash-colour; the legs are dusky, and very slightly covered with hair; the fore feet, as in the brown rat, have only four toes, with a small claw in place of a fifth; the tail is nearly naked, coated with a scaly skin, and marked into numerous divisions or rings. Like the former species, this animal breeds frequently, and commonly brings about six or seven young at a time. Sometimes they increase so fast as to overstock the place of their abode, in which case they fight and devour each other. It is said that this is the reason why these animals, after being extremely troublesome, sometimes disappear suddenly. Various are the methods made use of for the expulsion of rats from the places they frequent; among which none is more singular than that mentioned by Gesner, who tells us he had been informed that if a rat is caught and a bell tied round its neck, and then set at liberty, it will drive away the rest wherever it goes. This expedient appears to be occasionally practised in modern times with success. A gentleman travelling through Mecklenburgh, about 30 years ago, was witness to the following curious circumstance in the post-house in New Stargard. After dinner the landlord placed on the floor a large dish of soup, and gave a loud whistle. Immediately there came into the room a mastiff, a fine Angora cat, an old raven, and a remarkably large rat, with a bell about its neck. The four animals went to the dish, and without disturbing each other, fed together; after which the dog, cat, and rat, lay before the fire, while the raven hopped about the room. The landlord, after accounting for the familiarity which existed among the animals, informed his guest that the rat was the most useful of the four, for the noise he made had completely freed the house from the rats and mice with which it was before infested.

4. Mus musculus, common mouse. The manners and appearance of this little animal are so universally known, that it seems almost unnecessary to particularise it by a formal description. It is a general inhabitant of almost every part of the Old Continent, but it is doubtful whether it is originally a native of America, though now sufficiently common in many parts of the New World, as well as in many of its scattered islands.

The mouse, though wild and extremely timid, is not of a ferocious disposition, but may be easily tamed, and soon after it has been taken, will begin to feed without fear, in the immediate presence of its captors. The white variety is frequently kept in a tame state, and receives an additional beauty from the bright red colour of its eyes; a particularity which generally accompanies the white varieties, not only of this tribe, but of many other quadrupeds.

The mouse is a prolific animal: the experiment of Aristotle is well known, and often quoted. He placed a pregnant mouse in a vessel of grain, and after a short space found in it no less than the number of 120, all which, he concluded, were the descendants of the mouse he had inclosed.

The fur of the mouse is remarkably soft and elegant, and the structure of the hair in this animal, as well as in the rat, and probably in many others of this genus, is singularly curious; each hair, when microscopically examined, appearing internally divided into a kind of transverse partitions, as if by the continuation of a spiral fibre; a structure very different from that of the hair of most other animals, and of which the particular nature seems not very distinctly understood.

Derham, in his Physico-Theology, conceives that this mechanism of a spiral fibre may serve for the "gentle evacuation of some humour out of the body;" and adds, that "perhaps the hair serves as well for the insensible perspiration of hairy animals as to fence against cold and wet." Whatever is the real nature or use of the above structure, its appearance cannot fail to excite astonishment in those who take the pains of examining it with a good microscope, by which they will obtain a clear idea of this curious appearance.

In Aldrovandus, who relates the circumstance from Gesner, we meet with a direction for changing, as it were, a mouse into a cat, by making it the incessant persecutor and enemy of the rest of its species. This is to be effected by placing several mice together in a vessel without food, when, after a certain space, they will be so stimulated by hunger as to destroy each other: the surviving animal being then liberated, will, according to this author, become the most destructive enemy of his own tribe, and will kill every one he meets. Another singular and most cruel experiment is quoted by Aldrovandus from Mizaldus, who tells us, that if two or three mice are shut up in an earthen pot, and placed over a fire, the shrill cries which they utter will attract the mice in the other parts of the house, and cause them to precipitate themselves into the fire. Whatever truth there may be in this experiment, it is certain that, on the shrill cry of distress uttered by one of these animals kept with several others in a cage, the rest will frequently attack and destroy it.

5. Mus sylvaticus, wood mouse. This animal chiefly frequents dry and elevated grounds, and is found in woods and fields in great plenty. It appears to be common in all the temperate parts of Europe, and even in Russia. It sometimes varies in size, individuals being occasionally met with which exceed the rest in magnitude, though differing in no other respect. Its general length is about four inches and a half from nose to tail, and the tail, which is slightly covered with hair, measures four inches. The colour of the animal is a yellowish brown above and whitish beneath; the colours being pretty distinctly marked or separated; the eyes are full and black, and the snout rather blunt. These animals retire into holes among brushwood, and under the trunks of trees, where they amass great quantities of acorns, nuts, and beech-mast. According to Buffon, a whole bushel has sometimes been found in a single hole. These holes are about a foot or more under ground, and are often divided into two apartments; the one for living in alone with their young, the other for a magazine of provisions. Considerable damage is often done to plantations by these animals, which carry off new-sown acorns, &c. The count de Buffon affirms, that in France more mischief is done by these creatures than by all the birds and other animals put together; and adds, that the only way to prevent this is by laying traps, at ten paces asunder, through the whole extent of the sown ground. No other apparatus, he says, is necessary than a roasted walnut, placed under a stone supported by a stick: the animals come to eat the walnut, which they prefer to acorns; and as the walnut is fixed to the stick, whenever they touch it, the stone falls and kills them. The same expedient may be as successfully used for the destruction of the short-tailed field mouse, which likewise commits great havoc in fields and plantations. When the count de Buffon first practised this experiment, he desired that all the field mice thus taken in traps might be brought to him, and found with astonishment, that above 100 were taken each day from a piece of ground consisting only of about 40 of our acres. From the 15th of November to the 8th of December, above 2000 were destroyed in this manner. When the frost becomes severe, they retire into their holes, and feed on the stores they have collected. They abound, like many other animals of this genus, chiefly in autumn, and are far less common in the spring; for if provisions happen to fail them in the winter, it is thought that they destroy each other; a circumstance which is known occasionally to take place in many other species.

The long-tailed field mouse is a very prolific animal, breeding more than once a year, and often producing litters of ten at a time. In one of their holes have been found two females, with 20 young. Specimens have sometimes been seen perfectly white, with red eyes.

6. Mus messorius, harvest mouse. This small species seems to have escaped the notice of British naturalists till it was observed by the late Mr. Gilbert White, of Selburne in Hampshire, in which county it is frequent. Mr. White, in the year 1767, communicated the animal to Mr. Pennant, who introduced it into the British Zoology.

"These mice," says Mr. White, "are much smaller and more slender than the mus domesticus medius of Ray, and have more of the squirrel or dormouse colour; their belly is white; a straight line along their sides divides the shades of their back and belly. They never enter into houses, are carried into ricks and barns with the sheaves, abound in harvest, and build their nest amidst the straws of corn above ground, and sometimes in thistles. They breed as many as eight at a litter, in a little round nest composed of the blades of grass or wheat. One of these nests was procured in the autumn of 1767, most artificially platted, and composed of the blades of wheat, perfectly round, and about the size of a cricket-ball, with the aperture so ingeniously closed, that there was no discovering to what part it belonged. It was so compact and well filled, that it would roll across the table without being discomposed, though it contained eight little mice that were naked and blind. As this nest was perfectly full, how could the dam come at her litter respectively, so as to administer a teat to each? Perhaps she opens different places for that purpose, adjusting them again when the business is over; but she could not possibly be contained herself in the ball with her young, which moreover would be daily increasing in bulk. This wonderful procreant cradle, an elegant instance of the effect of instinct, was found in a wheat-field, suspended in the head of a thistle."

Mr. White adds, that "though these animals hang their nests for breeding up amidst the straws of standing corn, above ground, yet in the winter they burrow deep in the earth, and make warm beds of grass; but their grand rendezvous seems to be in corn-ricks, into which they are carried in harvest." A neighbour of Mr. White's housed an oat-rick, in which were some hundreds assembled under the thatch. The measure of the animal is just two inches and a quarter from nose to tail, and the tail is just two inches long. Two of them in a scale just weighed down a copper halfpenny, which was about the third of an ounce avoirdupois; so that they may be considered as the smallest of the British quadrupeds.

7. Mus minutus, minute mouse. This species, according to Dr. Pallas, is frequent in the birch-woods of Siberia, as well as in many of the temperate parts of Russia, frequenting corn-fields and barns. Its general colour is a deep tawny above and white below; the nose is sharpish and of a dusky colour, with a whiteness at the corners of the mouth; the ears are hid in the fur; the feet grey; the length from nose to tail is little more than two inches, and the weight not half a dram. Those found in Siberia are of a richer or more fulvous colour than those of other regions. This animal, Dr. Pallas says, is very frequent in autumn and winter in corn-ricks and about granaries, and is often found intermixed with the mus agrarius, inhabiting similar places. It seems extremely nearly allied to the harvest mouse, and it is not impossible that it may in reality be the same animal, the differences appearing almost too slight for a specific distinction.

8. Mus amphibius, water rat. The water rat is a general inhabitant of the temperate, and even the colder, parts of Europe and Asia, and occurs also in North America, frequenting rivers and stagnant waters, and forming its burrows in the banks. It is of a thicker and shorter form than many others of this genus, and has somewhat of the shape of a beaver. Mr. Ray, following an error of Willughby, describes it as having the forefeet webbed; and Linnæus, in his Systema Naturæ, characterizes it from that very circumstance, but acknowledges that he had not himself examined the animal. In reality, however, there is no such appearance in the feet of the water rat, and the notion seems to have been hastily adopted from observing the facility with which it swims and dives. The general length of the water rat is about seven inches, and the tail about five. Its colour is blackish-ferruginous above, and deep cinereous beneath; the nose is thick and blunt, the eyes small, the ears rounded and hid in the fur. In colour it appears to vary in different regions, being sometimes nearly black, and sometimes paler than usual. It also varies as to size, and the varieties have been mistakenly considered as distinct species. This animal never frequents houses, but confines itself to the banks of waters, and is supposed to live on fish, frogs, &c. and probably on various roots and other vegetable substances. Dr. Pallas, however, is unwilling to admit that it preys at all upon fish, though reported so to do by the count de Buffon and others. At some seasons of the year it is observed to have a musky scent. The female produces her young in April, and generally brings about five or six at a time. The measures of this species, as given by Mr. Schreber, are as follow, viz. from nose to tail six inches and a half, and of the tail three inches.

9. Mus lemmus, lemming rat. The wonderful migrations of this species have long rendered it celebrated in the annals of natural history. It is remarkable, however, that no accurate figure of it was published till Dr. Pallas caused it to be engraved in his excellent work on the Glires.

The first describer of the lemming seems to have been Olaus Magnus, from whom several of the older naturalists have copied their accounts. Afterwards Wormius gave a more particular description; since which, Ricaut, in the Philosophical Transactions, Linnæus, in the Acta Holmiensia, and Dr. Pallas, in his publication before mentioned, have still farther elucidated its history and manners. See Plate Nat. Hist. fig. 280.

The lemming differs in size and colour according to the regions it inhabits: those which are found in Norway being almost as large as a water rat, while those of Lapland and Siberia are scarce larger than a field mouse; the Norwegian measuring more than five inches from nose to tail, while those of Lapland and Siberia scarce exceed three. The colour of the Norway kind is an elegant variegation of black and tawny on the upper parts, disposed in patches and clouded markings; the sides of the head and the under parts of the body being white, the legs and tail greyish. In the Lapland kind the colour is chiefly a tawny brown above, with some indistinct dusky variegations, and beneath of a dull white; the claws are also smaller than in the Norwegian animal. The head of the lemming is large, short, thick, and well furred; the snout very obtuse; the ears very small, rounded, and hid in the fur; the eyes small; the neck short and broad; the body thick; and the limbs short and stout, especially the fore legs; the fore-feet are broad, furnished with five toes, which have strong, compressed, and somewhat crooked claws, of which the three middle ones are longer than the rest; on the hind-feet are also five toes, with smaller claws than those of the fore-feet; the tail is very short, thick, cylindric, obtuse, and covered with strong hairs, disposed like those of a pencil at the tip.

The natural or general residence of the lemming is in the Alpine or mountainous parts of Lapland and Norway, from which tracts, at particular but uncertain periods, it descends into the plains below in immense troops, and by its incredible numbers becomes a temporary scourge to the country, devouring the grain and herbage, and committing devastations equal to those caused by an army of locusts. These migrations of the lemming seldom happen oftener than once in ten years, and in some districts still less frequently, and are supposed to arise from an unusual multiplication of the animals in the mountainous parts they inhabit, together with a defect of food; and, perhaps, a kind of instinctive prescience of unfavourable seasons, for it is observable that their chief migrations are made in the autumn of such years as are followed by a very severe winter. The inclination or instinctive faculty which induces them, with one consent, to assemble from a whole region, collect themselves into an army, and descend from the mountains into the neighbouring plains, in the form of a firm phalanx, moving on in a straight line, resolutely surmounting every obstacle, and undismayed by every danger, cannot be contemplated without astonishment. All who have written on the subject agree that they proceed in a direct course, so that the ground along which they have passed appears at a distance as if it had been ploughed; the grass being devoured to the very roots, in numerous stripes, or parallel paths, of one or two spans broad, and at the distance of some ells from each other. This army of mice moves chiefly by night, or early in the morning, devouring the herbage as it passes, in such a manner that the surface appears as if burnt. No obstacles which they happen to meet in their way have any effect in altering their route; neither fires, nor deep ravines, nor torrents, nor marshes or lakes: they proceed obstinately in a straight line; and hence it happens that many thousands perish in the waters, and are found dead by the shores. If a rick of hay or corn occurs in their passage, they eat through it; but if rocks intervene which they cannot pass, they go round, and then resume their former straight direction. If disturbed or pursued while swimming over a lake, and their phalanx separated by oars or poles, they will not recede, but keep swimming directly on, and soon get into regular order again; and have even been sometimes known to endeavour to board or pass over a vessel. On their passage over land, if attacked by men, they will raise themselves up, uttering a kind of barking sound, and fly at the legs of their invaders, and will fasten so fiercely at the end of a stick, as to suffer themselves to be swung about before they will quit their hold; and are with great difficulty put to flight. It is said that an intestine war sometimes takes place in these armies during their migrations, and that the animals thus destroy each other.

The major part, however, of these hosts, is destroyed by various enemies, and particularly by owls, hawks, and weazels, exclusive of the numbers which perish in the waters; so that but a small number survive to return, which they are sometimes observed to do, to their native mountains.

In their general manner of life they are not observed to be of a social disposition, but to reside in a kind of scattered manner, in holes beneath the surface, without laying up any regular provision, like some other animals of this tribe. They are supposed to breed several times in a year, and to produce five or six at once. It has been observed that the females have sometimes brought forth during their migrations, and have been seen carrying some in their mouths, and others on their backs. In some parts of Lapland they are eaten, and are said to resemble squirrels in taste.

It was once believed that these animals fell from the clouds at particular seasons, and some have affirmed that they have seen a lemming in its descent; but an accident of this kind is easily accounted for, on the supposition of a lemming escaping now and then from the claws of some bird which had seized it, and thus falling to the ground; a circumstance which is said not unfrequently to take place when the animals are seized by crows, gulls, &c.

10. Mus œconomicus, œconomic rat. The œconomic rat, so named from its provident disposition, and the skill with which it collects its provisions, is a native of Siberia, inhabiting that country in vast abundance, and even extending as far as Kamtschatka. Its curious history has been given with great exactness by Dr. Pallas: who informs us that these little animals make their burrows with wonderful skill, immediately below the surface, in soft turfy soils; forming a chamber, of a flattish arched form, of a small height, and about a foot in diameter, to which they sometimes add as many as thirty small pipes or entrances, and near the chamber they frequently form other caverns, in which they deposit their winter stores; these are said to consist of various kinds of plants, even of some species which are poisonous to mankind. They gather them in summer, harvest them with great care, and even sometimes bring them out of their cells in order to give them a more thorough drying in the sun. The chief labour rests on the females; the males during the summer wandering about in a solitary state, inhabiting some old nests occasionally, and living during that period on berries, without touching the hoards, which are reserved for winter, when the male and female reside together in the same nest. They are said to breed several times in the year, the female producing two or three young at a time.

The migrations of this little species are not less extraordinary than those of the lemming, and take place at uncertain periods. Dr. Pallas imagines that the migrations of those inhabiting Kamtschatka may arise from some sensations of internal fire in that volcanic country, or from a prescience of some unusual and bad season. Whatever is the cause, the fact is certain. At such periods they gather together, during the spring season, in surprising numbers, except the few that reside about villages, where they can pick up some subsistence; and this makes it probable that their migrations, like those of the lemming, are rather owing to want of food. The mighty host proceeds in a direct course westward, occasionally swimming with the utmost intrepidity over rivers, lakes, and even arms of the sea. During these perilous adventures, some are drowned, and others destroyed by water-fowl, fish, &c.: those which escape rest a while to bask, dry their fur, and refresh themselves, and then again set out on their migration. It is said that the inhabitants of Kamtschatka, when they happen to find them in this fatigued situation, treat them with the utmost tenderness, and endeavour by every possible method to refresh and restore them to life and vigour. Indeed none of the smaller animals are so much esteemed by the Kamtschadales as these, since to their labours they owe many a delicious repast, robbing their hoards in autumn, and leaving there some kind of provision in return, accompanied by some ridiculous presents by way of amends for the theft. As soon as the migrating host of these animals has crossed the river Penschim, at the head of the gulph of that name, it turns southward, and reaches the rivers Judoma and Ochot about the middle of July: the space thus traversed appears astonishing, on consulting the map of the country. The flocks during this time are so numerous that an observer has waited two hours to see them all pass. Their return into Kamtschatka is in October, and is attended with the utmost festivity and welcome on the part of the natives, who consider their arrival as a sure prognostic of a successful chace and fishery; and they are said equally to lament their migrations, which are usually succeeded by rainy and tempestuous weather.

This curious species is generally of a tawny colour, darker on the back, and lighter on more approaching to an ash-coloured whiteness beneath: its usual length is about four inches and a quarter, and the tail one inch; its limbs are strong; its eyes small, its ears naked, very short and round, and almost hid beneath the fur of the head.

This animal is also supposed to be an inhabitant of Iceland; at least a species which must be greatly allied to it is found in that country, and is said to be particularly plentiful in the wood of Husafels. In that country, where berries are but thinly dispersed, the little animals are obliged to cross rivers to make their distant foraging excursions, and in their return are obliged to repass the stream; their manner of performing which is thus related by Mr. Olaffen, from the accounts of others, communicated to himself:

"The party, consisting of from six to ten, select a flat piece of dried cow-dung, on which they place the berries they have collected in a heap, on the middle; and then, by their united force, drawing it to the water's edge, launch it, and embark, placing themselves round the heap, with their heads joined over it, and their backs to the water; their tails pendant in the stream, and serving the purpose of rudders."

11. Mus socialis, social mouse. The social mouse is a native of the Caspian deserts between the Volga and the Yaik, and the country of Hircania. It lives in low sandy situations, in large societies; the ground in many places being covered with the little hillocks formed by the earth cast out in forming the burrows, which are said to be about a span deep, with eight or more passages. The animals are always observed to live in pairs, or with a family; they are fond of tulip-roots, which form a principal article of their food. They appear chiefly in the spring, when they are very numerous, but are rarely seen in autumn, and are supposed either to migrate in autumn or to conceal themselves among the bushes, &c. and in the winter to shelter themselves in hay-ricks. The head in this species is thick, and the nose blunt; the whiskers white; the ears oval and naked; the limbs short and strong, and the tail slender. The upper parts are of a light grey, and the under white.

12. Mus cricetus, hamster rat. Of the pouched rats the hamster is the most remarkable, and indeed is the only European species provided with those peculiar receptacles, which are situated on each side the mouth, and when empty are so far contracted as not to appear externally, but when filled resemble a pair of tumid bladders, having a smooth veiny surface, concealed, however, under the fur or skin of the cheeks, which bulge out extremely in this state. They are so large as to hold the quantity of a quarter of a pint, English measure.

The general size of the hamster is nearly that of a brown or Norway rat, but it is of a much thicker form, and has a short tail. Its colour is a pale reddish brown above, and black beneath. The muzzle is whitish, the cheeks reddish, and on each side the body are three moderately large oval white spots, of which those on the shoulders are the largest; the ears are moderately large and rounded, and the tail almost bare, and about three inches long; on the fore-feet are four toes, with a claw in place of a fifth, and on the hind-feet are five toes. Sometimes the hamster varies in colour, being found either black with a white muzzle, or of a pale yellowish white. The male is always much larger than the female. On each side the lower part of the back is an almost bare spot, covered only with very short down.

The hamster inhabits Siberia and the south of Russia. It is also found in Poland, as well as in many parts of Germany. They are very destructive in some districts, devouring great quantities of grain, which they carry off in their cheek-pouches, and deposit in their holes, in order to devour during the autumn. Their habitations, which they dig to the depth of three or four feet, consist of more or fewer apartments, according to the age of the animal: a young hamster makes them hardly a foot deep; an old one sinks them to the depth of four or five feet, and the whole diameter of the residence, taking in all its habitations, is sometimes eight or ten feet. The principal chamber is lined with dried grass, and serves for a lodging; the others are destined for the preservation of provisions, of which he amasses a great quantity during the autumn. Each hole has two apertures; the one descending obliquely, and the other in a perpendicular direction; and it is through this latter that the animal goes in and out. The holes of the females, who never reside with the males, are somewhat different in their arrangement, and have more numerous passages. The female breeds two or three times a year, producing five or six, and sometimes as many as sixteen or eighteen. The growth of the young is rapid, and they are soon able to provide for themselves.

The hamster feeds on all kinds of herbs and roots, as well as on grain, and even occasionally on the smaller animals. "In harvest-time (says Mr. Allamand) he makes his excursions for provision, and carries every article he can find into his granary. To facilitate the transportation of his food, nature has provided him with two pouches in the inside of each cheek. On the outside these pouches are membranous, smooth, and shining; and in the inside are a great many glands, which continually secrete a certain fluid, to preserve their flexibility, and to enable them to resist any accidents which may be occasioned by the roughness or sharpness of particular grains."

On the approach of winter the hamster retires into his subterraneous abode, the entry of which he shuts up with great care; and thus remaining in a state of tranquillity, feeds on his collected provision till the frost becomes severe; at which period he falls into a profound slumber, which soon grows into a confirmed torpidity, so that the animal continues rolled up, with all its limbs inflexible, its body perfectly cold, and without the least appearance of life. In this state it may even be opened; when the heart is seen alternately contracting and dilating, but with a motion so slow as to be scarce perceptible, not exceeding 15 pulsations in a minute, though in the waking state of the animal it beats 150 pulsations in the same time. It is added that the fat of the creature has the appearance of being coagulated, that its intestines do not exhibit the smallest symptoms of irritability on the application of the strongest stimulants, and the electric shock may be passed through it without effect. This lethargy of the hamster has been generally ascribed to the effect of cold alone; but late observations have proved, that unless at a certain depth beneath the surface, so as to be beyond the access of the external air, the animal does not fall into its state of torpidity, and that the severest cold on the surface does not affect it. On the contrary, when dug up out of its burrow, and exposed to the air, it infallibly awakes in a few hours. The waking of the hamster is a gradual operation: he first loses the rigidity of his limbs; then makes profound inspirations, at long intervals; after this he begins to move his limbs, opens his mouth, and utters a sort of unpleasant rattling sound. After continuing these operations for some time, he at length opens his eyes, and endeavours to rise; but reels about for some time, as if in a state of intoxication, till at length, after resting a small space, he perfectly recovers his usual powers. This transition from torpidity to activity requires more or less time, according to the temperature of the air, and other circumstances. When exposed to a cold air, he is sometimes two hours in waking; but in a warmer air the change is effected in half the time.

The manners of the hamster are generally represented as far from pleasing. No society appears to exist among these animals. They are naturally very fierce, and make a desperate defence when attacked: they also pursue and destroy every animal which they are capable of conquering, not excepting even the weaker individuals of their own species. They are said to be particularly fond of the seeds of liquorice, and to abound in the districts where that plant is cultivated. According to Mr. Sultzer, they abound to such a degree in Gotha, that in one year 11,564, in another 54,429, and in a third 80,139 of their skins were delivered in the Hotel de Ville of that capital, where the hamster is proscribed on account of the devastations it commits among the corn.

13. Mus bursarius, Canada rat. This, which is a species but lately discovered, seems to be the most remarkable of all the pouched rats for the proportional size of the receptacles. It is a native of Canada, and is about the size of a brown or Norway rat, and is of a pale greyish-brown colour, rather lighter beneath; the length to the tail is about nine inches, and that of the tail, which is but slightly covered with hair, about two inches; the legs are short; the fore-feet strong, and well adapted for burrowing in the ground, having five claws, of which the three middle ones are very large and long; the interior much smaller, and the exterior very small, with a large tubercle or elbow beneath it. The claws on the hind-feet are comparatively very small, but the two middle are larger than the rest, and the interior one is scarce visible; the teeth are extremely strong, particularly the lower pair, which are much longer than the upper; the ears are very small. This species is described in the 5th volume of the Transactions of the Linnæan Society; but we must observe that by some oversight in the conduct of the figure there given, the claws on the fore-feet are represented as only three in number, and are somewhat too long, weak, and curved. A more faithful representation

is given in Dr. Shaw's excellent work, which is accompanied by an outline of the head, in its natural size, in order to shew the teeth and cheek-pouches. The manners of this species are at present unknown; but it may be concluded that it lays in a stock of provisions, either for autumnal or winter food. The pouches of the individual specimen above described, when first brought to governor Prescot, were filled with a kind of earthy substance: it is, therefore, not improbable that the Indians who caught the animal might have stuffed it thus, in order to preserve it in its utmost extent.

14. Mus typhlus, blind rat. This is perhaps one of the largest and most remarkable of its tribe, measuring between seven and eight inches in length, and being entirely destitute both of eyes and tail; the defect of the former is a very singular circumstance, and the animal perhaps affords the only instance of a truly blind or eyeless quadruped. In the mole, the eyes, however small and deeply seated, are yet perfect in their kind, and though not calculated for acute vision, still enable the animal to avoid the danger of exposure; but in the quadruped now under consideration, there are merely a pair of subcutaneous rudiments of eyes, smaller than poppy-seeds, and covered with a real skin. It is probable, however, that even these minute organs are sufficient to give an obscure perception of light, and to enable the animal to consult its safety by generally continuing beneath the surface. The external ears are also wanting, and the foramina leading to the internal organs are very small, entirely hid by the fur, and situated at a great distance backward. There is scarce any distinction between the head and neck, and the whole form of the animal, like that of the mole, is calculated for a subterraneous life; the body being cylindric, the limbs very short, and the feet and claws, though small and weak in comparison with those of moles, yet calculated for digging or burrowing in the ground. The colour of the animal is a greyish brown; the fur, which is very thick, soft, and downy, being dusky toward the roots, and greyish toward the tips; the head is lighter and the abdomen darker than the other parts; the lower lip is also whitish, and sometimes a white mark extends along the forehead; the front-teeth are very large, and are naturally bare or exserted; the lower pair being much longer than the upper. This singular species is a native of the southern parts of Russia, where it burrows to a great extent beneath the surface, forming several lateral passages, by which it may pass in quest of roots, &c. It is said to feed in particular on the roots of the chærophyllum bulbosum. In the morning hours it sometimes quits its hold to bask in the sunshine, and if disturbed, instantly takes refuge beneath the surface; burrowing with great agility, and frequently in a perpendicular direction. Its bite is very severe when attacked. It has no voice, but emits a kind of snorting sound, and gnashes its large teeth in a menacing manner, raising its head at the same time. The female is said to produce from two to four young.

15. Mus Capensis, Cape rat. In its general shape, this animal is not unlike the great sand rat first described, and is equally common about the Cape of Good Hope; but it is far inferior in size, measuring about seven inches to the tail, which is very short, nearly white, and flattish. The general colour of this species is a dusky rufous ash-brown, paler or more inclining to whitish beneath; the end or tip of the nose is naked and black, the remainder white, and on each side are several strong white bristles; the chin, lower sides of the cheeks, and spaces round the eyes, are also white, and on the hind part of the head is an oval white spot; the teeth are naturally exserted or naked, and are similar in form to those of the great sand rat. In its manners and way of life, the animal is also similar to that species; and is very destructive to gardens, flinging up hillocks, and eating various kinds of roots.

MUSA, *the plantain tree*, a genus of the monœcia order, in the polyandria class of plants, and in the natural method ranking under the 8th order, scitamineæ. The calyx of the male hermaphrodite is a spatha or sheath; the corolla is dipetalous; the one petal erect and quinquedentate; the other nectariferous, concave, and shorter: there are six species, five of which are perfect; one style; the germen inferior and abortive. The female hermaphrodite has the calyx, corolla, filaments, and pistil, of the male hermaphrodite, with only one filament perfect; the berry is oblong, and three-angled below. There are three species:

1. Musa paradisiaca, is cultivated in all the islands of the West Indies, where the fruit serves the Indians for bread; and some of the white people also prefer it to most other things, especially to the yams and cassada bread. The plant rises with a soft stalk 15 or 20 feet high; the lower part of the stalk is often as large as a man's thigh, diminishing gradually to the top, where the leaves come out on every side: these are often eight feet long, and from two to three broad, with a strong fleshy mid-rib, and a great number of transverse veins running from the mid-rib to the borders. The leaves are thin and tender, so that where they are exposed to the open air, they are generally torn by the wind; for as they are large, the wind has great power against them: these leaves come out from the centre of the stalk, and are rolled up at their first appearance; but when they are advanced above the stalk, they expand and turn backward. As these leaves come up rolled in this manner, their advance upward is so quick, that their growth may almost be discovered by the naked eye: and if a fine line is drawn across level with the top of the leaf, in an hour the leaf will be near an inch above it. When the plant is grown to its full height, the spikes of flowers appear in the centre, which is often near four feet long. The flowers come out in bunches, those in the lower part of the spike being the largest; the others diminish in their size upward. Each of these bunches is covered with a sheath of a fine purple colour, which drops off when the flowers open. The upper part of the spike is made up of male flowers, which are not succeeded by fruit, but fall off with their covers. The fruit or plantain is about a foot long, and an inch and a half or two inches diameter: it is at first green, but when ripe pale-yellow. The skin is tough; and within is a soft pulp of a luscious sweet flavour. The spikes of the fruit are often so large as to weigh upwards of 40lb. The fruit of this sort is generally cut before it is ripe. The green skin is pulled off, and the heart is roasted in a clear fire for a few minutes, and frequently turned: it is then scraped, and served up as bread. Boiled plantains are not so palatable.

This tree is cultivated on a very extensive scale in Jamaica, without the fruit of which, Dr. Wright says, the island would scarce be habitable, as no species of provision could supply their place. Even flour or bread itself would be less agreeable, and less able to support the laborious negro, so as to enable him to do his business, or to keep in health. Plantains also fatten horses, cattle, swine, dogs, fowls, and other domestic animals. The leaves, being smooth and soft, are employed as dressings after blisters. The water from the soft trunk is astringent, and employed by some to check diarrhœas. Every other part of the tree is useful in different parts of rural economy. The leaves are used for napkins and table-cloths, and are food for hogs.

2. Musa sapientum, *the banana tree.* This species differs from the preceding in having its stalks marked with dark-purple stripes and spots. The fruit is shorter, straighter, and rounder; the pulp is softer, and of a more luscious taste. It is never eaten green; but when ripe it is very agreeable, either eaten raw or fried in slices as fritters; and is relished by all ranks of people in the West Indies. Both these plants were carried to the West Indies from the Canary Islands, whither, it is believed, they had been brought from Guinea, where they grow naturally. They are also cultivated in Egypt, and in most other hot countries, where they grow to perfection in about ten months from their first planting to the ripening of their fruit. When their stalks are cut down, several suckers come up from the roots, which in six or eight months produce fruit; so that by cutting down the stalks at different times, there is a constant succession of fruit all the year. In Europe some of these plants are raised by gentlemen who have hot-houses capacious enough for their reception, in many of which they have ripened their fruit very well; but as they grow very tall, and their leaves are large, they require more room in the stove than most people are willing to allow them. They are propagated by suckers, which come from the roots of those plants that have fruited; and many times the younger plants, when stinted in growth, also put out suckers. The fruit of this tree is four or five inches long, of the size and and shape of a middling cucumber, and of a high, grateful flavour: the leaves are two yards long, and a foot broad in the middle; they join to the top of the body of the tree, and often contain in their cavities a great quantity of water which runs out upon a small incision being made into the tree, at the junction of the leaves. Bananas grow in great bunches, that weigh 12 lb. and upwards. The body of the tree is so porous as not to merit the name of wood; the tree is only perennial by its roots, and dies down to the ground every autumn. When the natives of the West Indies (says Labat) undertake a voyage, they make provision of a paste of banana, which, in ease of need, serves them for nourishment and drink: for

this purpose they take ripe bananas, and having squeezed them through a fine sieve, form the solid fruit into small loaves, which are dried in the sun or in hot ashes, after being previously wrapped up in the leaves of Indian flowering-reed.

3. Musa troglodytarum, has a scarlet spathe and scarlet berry, but not eatable.

MUSCA, *fly*, a genus of insects of the order diptera. The generic character is: mouth formed into a fleshy proboscis, with two lateral lips; palpi, none.

The vast extent of the genus musca makes it necessary to divide the whole into different assortments, in order to the more ready investigation of the species. These divisions are instituted from the form of the antennæ, which are either simple (without any lateral hair or plume), or armed (that is, furnished with a lateral hair or plume). These divisions are farther separated into others, according to the more or less downy or hairy appearance of the insects.

The first section of this genus comprehends such flies as have simple antennæ.

The larvæ, in the different tribes of flies, differ far more in habit than the complete insects, some being terrestrial, and others aquatic. Those of the more common kinds are emphatically distinguished by the title of *maggots*, and spring from eggs deposited on various putrid substances. Several of the aquatic kinds are of singularly curious formation, and exhibit wonderful examples of the provision ordained by nature for the preservation of even the meanest and most seemingly contemptible of animals. Several are inhabitants of plants, feeding during this state on other living insects.

The general form of the chrysalis or pupa is that of an oval, differently modified, according to the species, and formed by the external skin of the larva, which hardens round the chrysalis. Some species, however, cast their skin before their change into the pupa state.

In this division one of the most remarkable species is the musca chamæleon, which is a large black fly, with a broad flattish abdomen, having the sides of each segment yellow, forming so many abrupt semibands across that part. It proceeds from an aquatic larva, of very considerable size, measuring two inches and a half in length, of a somewhat flattened shape, and of a brown colour, with a narrow or slender front, the body widening by degrees towards the middle, and from thence gradually tapering to the extremity or tail, which is terminated by a circle of radiating or diverging hairs. This larva is common in stagnant waters during the summer months, and passes into its chrysalis state without casting its skin, which dries over it, so as to preserve the former appearance of the animal in a more contracted state.

In this division also stands the musca vermileo, a middle-sized fly, of a somewhat lengthened form, with a distant resemblance to a tipua. It is of a dull yellow colour, with transparent wings; the thorax marked above by two black lines, and the abdomen by a triple series of black spots. The larva of this species measures above three quarters of an inch in length, and is of a pale yellowish-grey colour, slender or sharpened in front, and growing gradually broader towards the tail. It is found in the southern parts of Europe, and is not uncommon in some districts of France, and is remarkable for practising a method exactly similar to that of the hemerobius formicaleo in order to obtain its prey; excavating a circular pit or cavity in the dry sand, concealing itself beneath the centre, and thus waiting the arrival of any small insect which may happen to fall into it, and after absorbing its juices, throwing out the exhausted remains to a considerable distance from the verge of the cavity. This larva seems to have been first observed and described by Reaumur, in the Memoirs of the French Academy for the year 1752. It assumes the state of a chrysalis by casting its skin, which rolls to the hinder part of the body: the chrysalis is of a dull reddish colour, and is rounded or clubbed at the upper part, suddenly tapering from thence to the extremity, and after lying nine or ten days, gives birth to the included insect.

Of the downy or slightly haired flies with bristled antennæ, one of the most remarkable is the musca tenax, which is about the size of a drone, and of a brown colour, with transparent wings, and the first segment of the abdomen yellowish on each side. It proceeds from a larva of a very singular appearance, being a long-tailed brown maggot, of rather slow motion, measuring about three quarters of an inch in length, exclusive of the tail, which is extensile, and consists of a double tube, the exterior annulated into numerous segments, and the interior slender, and terminated by a circle of hairs, surrounding a spiraculum or air-hole. This maggot is seen in muddy stagnant waters, drains, and other places of the dirtiest description; and notwithstanding its unpleasing appearance, exhibits, when accurately examined, many particulars well worthy of admiration. The feet in particular, which are seven in number on each side, are wonderfully calculated for enabling the animal to ascend walls or other perpendicular places, in order to seek some proper situation in which it may undergo its change into chrysalis, being very broad, and beset on their under surface with numerous small hooked claws, giving it the power of clinging with security during its ascent.

Of this larva a particularity is stated on the authority of Linnæus, which, if true, may indeed well be numbered among the Miracula Insectorum (the title of the paper in the Amœnitates Academicæ, in which it is announced), viz. that being a frequent inhabitant of the turbid pulp used in the operation of paper-making, it is often exposed to the action of the wooden mallets used in the process, as well as squeezed in the strongest presses, and yet survives uninjured these seemingly destructive operations!!!

The above larva commonly changes to a chrysalis about the end of August, the skin contracting and drying round the body, and the tail continuing in a shrivelled state. After thus remaining about the space of a fortnight, it gives birth to the complete insect, which has so much the general appearance of a drone, that it is very frequently mistaken for such. It is extremely common during the month of September.

Musca pendula, which belongs also to this division of the genus, is a moderately large and very beautiful insect. Its colour is black, with four bright yellow stripes down the thorax, and three broad interrupted bars across the abdomen; or, in other words, this fly might be described as of a bright yellow colour, with the thorax marked by four longitudinal black lines, and the abdomen by three transverse ones, connected by a black stripe down the middle. Its larva, which is an inhabitant of stagnant waters, is of a still more remarkable appearance than that of the immediately preceding species, which it resembles in size, but is of a paler colour, and furnished with a tail of greater length, composed of a double tube, the interior of which is very slender, extensile at the pleasure of the animal to a vast length, and terminated by a very small spiracle. The length of this tube is therefore varied according to the greater or smaller depth at which the insect chooses to continue, the tip reaching to the surface, in order to supply the requisite quantity of air. Sometimes great numbers of these maggots are found coiled or twisted together by their tails in such a manner that it is by no means easy to separate any one from the rest. The chrysalis resembles that of the musca tenax, the remains of the tail being visible in a dried and contracted state. The complete insect is frequently seen on flowers during the autumnal season.

Among the hairy or bristly flies with plumed antennæ stands the well-known species called musca carnaria, or the common large blow-fly. This, as every one knows, deposits its eggs on animal flesh, either fresh or putrid. The larvæ or maggots hatch in about the space of a few hours, and when full-grown, which happens in eight or ten days, are of a white or yellowish-white colour with a slight tinge of pale-red, and of a lengthened shape, with a sharpened front, in which the mouth is situated, and from whence the body gradually enlarges in size to the last or terminal segment, which is of a very broad and flattened form, surrounded by several slightly prominent tips, and furnished with a pair of dusky specks resembling eyes; so that an inaccurate spectator might easily mistake this part for the head, and the proper head for the tail. When the animal changes to a chrysalis, the skin dries round it, and the whole assumes a completely oval form, and a reddish colour, soon changing into a reddish-brown. In ten days more the fly itself emerges, which is too well known to require particular description.

Musca vivipara greatly resembles the preceding, and is found in similiar situations, but is viviparous, disclosing small ready-formed larvæ instead of eggs, which in this species are hatched internally. This particularity is not confined to the present species, but has been observed in some others of this genus.

To this as well as the preceding has been applied the observation, *Tres muscæ consumunt cadaver equi æquè citò ac leo;* the number of larvæ proceeding from the flies, and the quick evolution of the successive broods, destroying the same quantity of flesh in a given time as the predacious quadruped, who devours a great quantity at certain intervals only, while the process of destruction continues with unremitted perseverance on the part of one or other of the respective races of flies.

Of the hair-flies with bristled antennæ, the musca grossa, the largest of European flies, affords a good example.

Musca flava, is one of the smallest but most elegant of the European flies; it is of a yellow colour, with bright gold-green eyes.

MUSCI, *Mosses*, one of the seven families or classes into which all vegetables are divided by Linnæus in the Philosophia Botanica, is the 2d order in the cryptogamia class, according to the sexual system.

The more perfect kinds of mosses are found in the shape of small but regular plants, divided into several branches, and clothed with leaves. these are of various forms and structures; some being broad and thin, others slender as hairs; some pellucid, others opaque; some smooth, others hairy. From the alæ of these leaves in some kinds, and from the summit of the stalks in others, there arise heads or capsules of various figure and structure, but all unicapsular; some of these are naked, and others covered with a calyptra- or hood; some stand on long pedicles, and others are placed close to the stalks. These heads are usually called capsulæ, which contain their seeds or farina; and their pedicles setæ, in the mnia, hypna, brya, and polytricha, &c. These capsules in some are covered with a calyptra or hood; in others they are naked. Of the first kind are the splachnum, polytrichum, mnium, bryum, hypnum, fontinalis, and buxbaumia; and of the latter sort, the lycopodium, porella, sphagnum, and phascum.

Some of the mosses, it is evident, approach to the nature of the plants which have their male and female parts in the same flower, and others to those which have them in different ones. After all, this tribe of plants, as well as the mushrooms, ferns, and seaweeds, is still inperfectly known. The characteristics of these plants, however, according to the sexual system, are, 1. Tops without filaments or threads. 2. The male flower, constituted by the presence of the antheræ or tops, placed apart from the female, either on the same or distinct roots. 3. The female roots, flowers deprived of the pistillum or pointal. 4. The seeds devoid of both lobes (cotyledones) and proper coverings, so that they exhibit the naked embryo.

This order is subdivided into 13 genera, from the presence or absence of the calyx, which in these plants is a veil or cover like a monk's cowl, that is placed over the male organs or tops of the stamina, and is denominated calyptra, from the sexes of the plants, which bear male and female flowers, sometimes on the same, sometimes on distinct roots; and from the manner of growth of the female flowers, which are sometimes produced singly, sometimes in bunches or cones.

The manner of seeding of mosses in general, may be more clearly understood from the description of that genus of them which has been traced through all its stages, and to which most of the others, though every genus has its distinct fructification in some respects, yet bear a very general analogy.

The genus already observed, is that called by Dr. Dillenius, the hypnum. The species of this are very numerous and common; but that particular one which was the subject of these observations, is the short-branched silky kinds, common on old walls; and called by that author in his History, hypnum vulgare, sericum, recurvum, capsulis erectis cuspidatis.

The head of this moss appears to the naked eye a small, smooth, brownish-yellow, oblong body, of about a ninth of an inch long; this is covered at its upper end with a membranaceous calyptra or hood, in shape resembling an extinguisher, or a funnel inverted. When this calyptra is taken off, and the head viewed with a microscope, the surface of it is seen to be ridged with longitudinal striæ. The basis of the head is of a deep orange-colour, and more opaque than the rest; and the top is bounded by an orange-coloured ring, swelling out something beyond the surface of the contiguous parts of the head. Good glasses show that in this head there are not wanting the parts essential to the fructification of what are usually called the more perfect plants. This ring is truly a monophyllous undulated calyx, within which arise sixteen pyramidal fimbriated stamina; these are of a pale-greenish colour, and are loaded with a whitish oval farina. The stamina all bend toward each other from their bases, and almost meet in a point at the tops. This is their appearance when the head is nearly ripe; and immediately under the arch formed by these stamina, is a cylindric hollow pistillum, through which the farina makes its way, and is dispersed among the seeds in the head. The fruit is a large capsule, filling every part of the membrane which shows itself on the outside of the head, and in most places is contiguous to it; this capsule is filled with perfect and very beautiful seeds; they are round, transparent when unripe, but afterwards opaque, and of a very beautiful green, which colour they retain even when dried.

When this head is first produced from the plant, the stamina are very slender, and stand erect; the head is scarcely any thicker than the stalk, and the calyptra covers it all over, to shield the tender substance of the farina from external injuries. As the farina afterwards swells in the stamina, the seeds in the head increase also in bulk, and by their increase the head is more extended in thickness; and the stamina are by this means separated farther and farther from each other at their bases, but bend inwards toward their points, so as to form a kind of arched covering over the stigma of the pistillum, which is single, and hence the farina falls as it ripens into the head, and impregnates the seeds.

The 11 principal genera are as follow: lycopodium, polytrichum, bryum, selagines, usneæ, mnium, byssi, sphagnum, hypna, confervæ, and fontinales. These are found growing on the barks of trees as well as on the ground.

Many of the mosses grow on rocks and barren places, and, rotting away, afford the first principles of vegetation to other plants, which could never else have taken root there. Others grow in bogs and marshes, and by continual increase and decay fill up and convert them either into fertile pastures, or into peat-bogs, the source of inexhaustible fuel to the polar regions. They are applicable also to many domestic purposes: the lycopodiums are some of them used in dyeing of yarn, and in medicine; the sphagnum and polytrichum furnish convenient beds for the Laplanders; and the hypnums are used in tiling of houses, stopping crevices in walls, packing up of brittle wares and the roots of plants for distant conveyance, &c.

MUSCICAPA, or FLY-CATCHER, a genus of birds belonging to the order of passeres. The bill is flatted at the base, almost triangular, notched at the upper mandible, and beset with bristles; the toes (generally) divided as far as their origin. There are 97 species; the most remarkable are:

1. The grisola, or spotted fly-catcher, about five inches and three quarters long. The head is large, of a brownish hue, spotted obscurely with black: the back is of a mouse-colour; the wings and tail are dusky; the breast and belly white. It is a bird of passage; appears here in the spring, breeds with us, and departs in September. It builds its nest against any part of a tree that will support it; often in the hollow caused by the decay of some large limb, hole in a wall, &c. also on old posts and beams of barns; and is found to return to the same place season after season. It lays four or five pale eggs marked with reddish. It feeds on insects, and collects them on the wing.

2. The flabellifera, or fan-tailed fly-catcher, is in length six inches and a half: the head is black, which colour descends on the back part lower than the nape, whence it passes forward in a narrow collar to the throat; the chin, throat, and sides of the neck, except where this collar passes, are white, and over the eye is a white streak like an eye-brow; the tail is longer than the body, the two middle feathers black, the others white; the legs are dusky. This species inhabits the southern isle of New Zealand; where it is seen constantly hunting after insects, and flies always with its tail in shape of a fan. It is easily tamed; and will then sit on any person's shoulder, and pick off the flies. See Plate Nat. Hist. fig. 281.

3. The caribonensis, or cat-bird, is somewhat bigger than a lark: length eight inches: bill black; the upper parts of the body and wings are of a deep brown; the under ash-coloured; the crown of the head is black; the tail is blackish; and the legs are brown. This species is found in Virginia in the summer-season, where it frequents shrubs rather than tall trees, and feeds on insects; its cry resembles that of a cat, whence the English name given it by Catesby.

4. The rubicollus, purple-throated fly-catcher, is about the size of a blackbird; the whole plumage is black, except the chin, throat, and fore part of the neck, on which is a large bed of beautiful crimson, inclining to purple; the legs are black. These birds inhabit Cayenne and other parts of South America; where they are found in flocks, and precede in general the toucans in their movements. They feed on fruits and insects; and are lively birds, always in action. They for the most part frequent the woods, like the toucans; and where the first are found, the others are seldom far off. See Plate Nat. Hist. fig. 283.

MUSCLE. See ANATOMY.

MUSCLES, *Insertion and force of the.* The all-wise Author of nature has furnished animals with limbs, moveable about the joints by means of muscular cords, inserted near the joint or centre of motion; the great wisdom of which will appear, from supposing the insertion to be at E (Plate Miscel. fig. 168.) near the wrist B, the muscle D E being either loose and separate from the bone D, A, B, or bound down to it by some ligament or fascia R; in either of which cases the bone A B cannot be turned up quite to the situation A H, unless the muscle D E is contracted or shortened to D M, which would not only be troublesome but even impossible. It would be troublesome, because the breadth and thickness of the arm would be vastly increased, so as to become as big as the belly of an animal. On the other hand, the structure of a muscle being such that it cannot be contracted but a little, seldom above two or three fingers'-breadth; such an insertion as that at E, which requires a contraction of about a foot and a half, would be altogether impossible. Therefore, in fact, we find the muscles inserted near the centre of motion, as at I, fig. 169.

In order to calculate the force of any muscle, we are to consider the bones as levers; and then the power or force of the muscle will be always to the resistance or weight it is capable of raising, as the greater distance of the weight from the centre of motion is to the lesser distance of the power. Hence, it being found by experiments, that a robust young man is able to suspend a weight R, equal to twenty-eight pounds, when the arm is extended in a supine and horizontal situation, we have this proportion, viz. the force of the muscle I D is to the weight R, = 28 ℔, as the distance D C is to the distance I C. But it is found, that D C, the length of the cubit and hand, is more than twenty times greater than I C, the distance of the muscle from the centre of motion. Therefore the force of the muscle I D, must be more than twenty times greater than the weight R, or more than 28 × 20 = 560 ℔.

Again, to find the force which the biceps and brachiæus muscles exert, when the humerus D A, (fig. 170.) is perpendicular to the horizon, we are first to consider what weight a man is capable of sustaining in this posture, viz. R = 35 pounds, and next the quantity of the distances C B, C I, which in this case are as 16 to 1. Therefore the force of these muscles is to the weight R = 35 pounds, as the distance C B = 16 is to the distance I C = 1; or the force is equal to 560, as before.

But what appears most wonderful is, the force of the muscles that move the lower jaw; which, when taken altogether, do not in a man exceed the weight of 1 pound, and yet exert a force equal to 534 pounds, and in mastiff-dogs, wolves, bears, lions, &c. their force is vastly superior, so as to break large bones, as they practise daily in their feeding.

The motions of the far greater part of the muscles are voluntary, or dependant on our will; those of a few others, involuntary. The former are called animal, the other natural motions. Finally, the motions of some of the muscles are of a mixed kind, partly animal and partly natural. Those muscles which perform the voluntary motions, receive nerves from the brain or spinal marrow: those which perform their motions involuntarily, have their nerves from the cerebellum; and those whose motion is partly voluntary, and partly involuntary, have theirs in part from the brain, and in part from the cerebellum. And as a muscle can no longer act when its nerve is either cut asunder or tied up, so the same absolute dependance it has on its artery: for from the experiments of Steno and others on living animals, it appears that in cutting or tying up the artery, the muscle in the same manner loses its whole power of action, as if the nerve had been cut or tied up.

MUSCOVY GLASS. See Mica.

MUSHROOM. See Agaricus.

MUSIC, a science which teaches the properties, dependances, and relations of melodious sounds; or the art of producing harmony and melody by the due combination and arrangement of those sounds. This science, when employed in searching the principles of this combination and succession, and the causes of the pleasure we receive from them, becomes very profound, and demands much patience, sagacity, and depth of thinking. It is generally supposed that the word music is derived from Musa, because it is previously believed that the invention of this art is to be attributed to the muses: but Diodorus derives it from an Egyptian name, intimating that music was first established as a science in Egypt after the Deluge, and that the first idea of musical sound was received from that produced by the reeds growing on the banks of the Nile, by the wind blowing into them. Others again imagine, that the first ideas of music were received from the warbling of birds. However this may really have been, it appears at least equally rational, to attribute its origin to mankind; since musical intonation, in the infancy of language, must often have been the natural result of passionate feeling, and since also we find that wherever there is speech there is song.

The antient writers on this science differ greatly as to its object and extent. In general, they give to it a much wider latitude than that which it obtains with us. Under the name of music they comprehended not only the melodious union of voices and instruments, but also the dance, gesture, poetry, and even all the other sciences. Hermes defines music to be the general knowledge of order; which was also the doctrine of Plato, who taught that every thing in the universe was music.

Music, however, properly so called, only concerns the due order and proportion of sounds; and is divided into two parts, the theoretical and the practical. Theoretical music comprehends the knowledge of harmony and modulation; and the laws of that successive arrangement of sound by which air, or melody, is produced. Practical music is the art of bringing this knowledge and those laws into operation, by actually disposing of the sounds, both in combination and succession, so as to produce the desired effect; and this is the art of composition: but practical music may, in fact, be said to extend still further, and to include not only the production of melodious and harmonious composition, but also its performance; and to such a facility in execution, and nicety of expression, has this department of practical music arrived at the present day, that its professors, generally speaking, hold a truly respectable rank in the various list of modern artists; and are highly, as well as most deservedly, esteemed by all lovers and patrons of musical taste and ingenuity.

MUSSÆNDA, a genus of the pentandria monogynia class and order. The cor. is funnel-form; stigma 2, thickish; berry oblong, inferior; seeds disposed in 4 rows. There are three species, shrubs of China.

MUSK. This substance is secreted into a kind, situated in the umbilical region of the quadruped called moschus moschifer (which see). Its colour is brownish red; its feel unctuous; its taste bitter; and its smell aromatic and intensely strong. It is partially soluble in water, which acquires its smell; and in alcohol, but that liquid does not retain the odour of musk. Nitric and sulphuric acids dissolve it, but destroy the odour. Fixed alkalies develope the odour of ammonia. Oils do not act on it. At a red heat it has the same fetid smell as urine. Its component parts have not been ascertained.

MUSKET, a fire-arm borne on the shoulder, and used in war. The length of a musket is fixed at three feet eight inches from the muzzle to the pan, and it carries a ball of 29 to 2 pounds.

In fortification, the length of the line of defence is limited by the ordinary distance of a musket-shot, which is about 120 fathoms; and the length of almost all military architecture is regulated by this rule. See Gunnery, Gun-smithery, and Rifle.

MUSKETOON, a kind of short thick musket, whose bore is the thirty-eighth part of its length: it carries five ounces of iron, or seven and a half of lead, with an equal quantity of powder. This is the shortest sort of blunderbuss.

MUSLIN, a fine thin sort of cotton cloth, which bears a downy nap on its surface. There are several sorts of muslins brought from the East Indies, and more particularly from Bengal.

MUSTELA, the *otter*, a genus of quadrupeds of the order feræ: the generic character is, foreteeth upper six, erect, acuter, distinct; lower six, obtuser, crowded, placed within; tongue smooth.

M. lutra, common otter. The common otter is found in almost every part of Europe, as well as in the colder regions of Asia; inhabiting the banks of rivers, and feeding principally on fish. It occurs also in the northern parts of America, and particularly in Canada, where it appears to arrive at a larger size than in Europe. In the river Euphrates, on the contrary, it is found to be no larger than a common cat; but it is probable, that this is in reality a different species, viz. the M. lutreola, or smaller otter, hereafter to be described. The length of the otter is nearly two feet from nose to tail, and of the tail about sixteen inches. Its colour is a deep brown, with a small light-coloured patch on each side the nose, and another under the chin. "The otter, (says Mr. Pennant) shews great sagacity in forming its habitation: it burrows under ground on the banks of some river or lake, and always makes the entrance of its hole under water, working upwards to the surface of the earth; and, before it reaches the top, makes several holts or lodges, that in case of high floods it may have a retreat, for no animal affects lying drier; and then makes a minute orifice for the admission of air. It is farther observed, that this animal, the more effectually to conceal its retreat, contrives to make even this little air-hole in the midst of some thick bush." Though the principal food of the otter consists of fish, yet it is said that in hard weather, when this its natural prey fails, it will attack the smaller quadrupeds, as well as poultry, &c. The otter is naturally a very fierce animal; and when hunted with dogs, as is sometimes the practice, will inflict very severe wounds on its antagonists. The female produces four or five young at a birth; this commonly happens early in the spring. The young otters, if taken at a very early age, may be successfully tamed, and taught by degrees to hunt for fish, and bring them to their master.

When the otter, in its natural or uneducated state, has caught a fish, it immediately draws it ashore, and devours the head and upper parts, leaving the remainder; and when in a state of captivity, will eat no fish but what is perfectly fresh, but will prefer bread, milk, &c.

2. M. lutreola, the smaller otter, very much resembles the common otter, but is smaller; the body is of a dusky colour, but with a considerable cast of tawny. In size it falls short of the common otter, measuring about a foot in length. In North America this species is known by the name of minx; and is said sometimes to leave the water, and prey on poultry, &c. in the manner of a polecat, biting off the heads and sucking the blood. It is said also to have a fetid smell. In Europe the smaller otter is chiefly found in Poland and Lithuania, living on fish, frogs, &c. Its fur is very valuable, and next in beauty to that of the sable.

3. M. lutris, the sea otter, is the largest of the otters, measuring about 3 feet from the nose to the tail, and the tail thirteen inches. The colour of this species is a deep, glossy, brownish black, the fur being extremely soft and very fine; on the forehead is generally a cast of greyish or silver-colour. According to Mr. Pennant, it is one of the most local animals we are acquainted with, being entirely confined between lat. 44. and 60. north; and between east long. from London, 126. to 150.; inhabiting, in great abundance, Bering's islands, Kamtschatka, the Aleutian and Fox islands, between Asia and America. They land also in the Kurile islands, but are never seen in the channel between the northeast of Siberia and America. It is supposed that they bring but one at a time. They are most extremely harmless animals, and are singularly affectionate to their young. They bring forth on land, and often carry the young one between their teeth; fondle them; and frequently fling them up, and catch them again in their paws; and before they can swim, the parents take them in their fore feet, and swim about on their backs. The young continues with its parent till it takes a mate.

This animal is killed for its skin, which is one of the most valuable of furs, being sold at the rate of from 14 to 25 pounds sterling each. They are said to be chiefly sold to the Chinese.

The sea otter is sometimes taken with nets, but is more frequently destroyed with clubs and spears.

4. M. fero, ferret, has eyes red and fiery. It inhabits Africa. In Europe it is tamed to catch rabbits, rats, &c. It procreates twice a year, and brings forth from 6 to 8 at a time. See Plate Nat. Hist. fig. 284.

M. erminea, stoat: inhabits Europe, the cold parts of Africa, Asia, and China; lives in heaps of stones, banks of rivers, hollow trees, and forests, especially of beech: preys on squirrels, mice, and small birds. Body about ten inches long; hair short, which in northern climates becomes white, except the outer half of the tail, which remains black. The fur is very valuable. See Plate Nat. Hist. fig. 286. There are 28 species of the mustela.

MUTE. If any person being arraigned on any indictment or appeal for felony, or on any indictment for piracy, shall upon such arraignment stand mute, or will not answer directly to the felony or piracy, he shall be convicted of the offence, and the court shall thereupon award judgment and execution, in the same manner as if he had been convicted by verdict or confession; and by such judgment shall have all the same consequences as a conviction by verdict or confession. 12 G. III. c. 20.

And the law is the same with respect to an arraignment for petit treason or larceny; for before this act, persons standing mute in either of these cases, were to have the like judgment as if they had confessed the indictment. 2 Inst. 177.

MUTILLA, a genus of insects, of the order hymenoptera; the generic character is, antennæ filiform; feelers four; the articulations obconic, seated on the tip of the lip; jaw membranaceous at the tip, lip projecting obconic; wings in most species obconic; body pubescent, thorax retuse behind; sting pungent, concealed. The M. helvola inhabits the Cape of Good Hope. See Plate Nat. Hist. fig. 287. There are 38 species.

MUST. See FERMENTATION.

MUTISIA, a genus of the class and order syngenesia polygamia superflua. The cal. is cylindric, imbricate; cor. of the ray oval, oblong; of the disk, trifid, down-feathered; recept. naked. There is one species, a climber of Peru.

MUTUAL PROMISE, is where one man promises to pay money to another, and he, in consideration thereof, promises to do a certain act, &c. &c. Such promises must be binding, as well on one side as the other; and both made at the same time. 1 Salk. 21.

MUTUS ET SURDUS, a person dumb and deaf, and being a tenant of a manor, the lord shall have the wardship and custody of him. But if a man be dumb and deaf, and have understanding, he may be grantor or grantee of lands, &c. 1 Co. Inst.

A prisoner deaf and dumb from his birth, may be arraigned for a capital offence, if intelligence can be conveyed to him by signs or symbols. Leach's Cr. Law, 97. See EVIDENCE.

MUTULE. See ARCHITECTURE.

MUTUUM, in the civil law, denotes a loan simply so called; or a contract introduced by the law of nations, whereby a thing consisting in weight, as bullion; in number, as money; or in measure, as corn, timber, wine, &c. is given to another upon condition that he shall return another thing of the same quantity, nature, and value, on demand. This, therefore, is a contract without reward; so that where use or interest arises, there must be some particular article in the contract whereon it is founded.

MUTINY, in a military sense, to rise against authority. Any officer or soldier who shall presume to use traiterous or disrespectful words against the sacred person of his majesty, or any of the royal family, is guilty of mutiny.

Any officer or soldier who shall behave himself with contempt or disrespect towards the general or other commander in chief of our forces, or shall speak words tending to their hurt or dishonour, is guilty of mutiny.

Any officer or soldier who shall begin, excite, cause, or join in, any mutiny or sedition in the troop, company, or regiment to which he belongs, or in any other troop, or company, in our service, or on any party, post, detachment, or guard, on any pretence whatsoever, is guilty of mutiny.

Any officer or soldier, who, being present at any mutiny or sedition, does not use his utmost endeavours to suppress the same, or coming to the knowledge of any mutiny, or intended mutiny, does not, without delay, give information to his commanding officer, is guilty of mutiny.

Any officer or soldier, who shall strike his superior officer, or draw, or offer to draw, or shall lift up any weapon, or offer any violence against him, being in the execution of his office, on any pretence whatsoever, or shall disobey any lawful command of his superior officer, is guilty of mutiny. See the articles of war.

MYA, the gaper, in zoology; a genus belonging to the order of vermes testacea, the characters of which are these. It has a bivalve shell gaping at one end; the hinge, for the most part, furnished with a thick, strong, and broad tooth, not inserted into the opposite valve. This animal is an ascidia. The most remarkable species are,

1. The declivis, or sloping mya, which has a brittle half-transparent shell, with a hinge slightly prominent near the opening, and sloping downwards. It inhabits the rivers of Europe. It is frequent about the Hebrides, and the fish is eaten there by the gentry.

2. The mya pictorum, has an oval brittle shell, with a single longitudinal tooth like a lamina in one shell, and two in the other; the breadth is a little above two inches, the length one. It inhabits rivers. The shells are used to put water-colours in, whence the name. Otters feed on this and the other fresh-water shells.

3. The margaritifera, or pearl mya, has a very thick, coarse, opaque shell; often much decorticated; oblong, bending inward on one side, or arcuated; black on the outside; usual breadth from five to six inches, length two and a quarter. It inhabits great rivers, especially those which water the mountainous parts of Great Britain. This shell is noted for producing quantities of pearl. There have been regular fisheries for the sake of this precious article in several of our rivers. Sixteen have been found within one shell. They are the disease of the fish, analogous to the stone in the human body. On being squeezed they will eject the pearl, and often cast it spontaneously in the sand of the stream. The river Conway was noted for them in the days of Camden.

Linnæus made a remarkable discovery relating to the generation of pearls in this fish. It is a fish that will bear removal remarkably well; and it is said, that in some places they form reservoirs for the purpose of keeping it, and taking out the pearl, which, in a certain period of time, will be again renewed. From observations on the growth of their shells, and the number of their annular laminæ or scales, it is supposed the fish will attain a very great age; 50 or 60 years are imagined to be a moderate computation. The discovery turned on a method which Linnæus found, of putting these shell-fish into a state of producing pearls at his pleasure; though the final effect did not take place for several years: he says that in five or six years after the operation, the pearl would have acquired the size of a vetch. We are unacquainted with the means by which he accomplished this extraordinary operation.

MYAGRUM, *Gold of Pleasure*, a genus of the siliculosa order, in the tetradynamia class of plants; and in the natural method ranking under the 39th order, siliquosæ. The silicula is terminated by an oblong style; the cell generally monospermous. There are ten species; but the most remarkable is the sativum, which grows naturally in cornfields in the south of France and Italy, and also in some parts of Britain. It is an annual plant; and is cultivated in Germany for the sake of the expressed oil of the seeds, which the inhabitants use for medicinal, culinary, and economical purposes. The seeds are a favourite food with geese. Horses, goats, sheep, and cows, eat the plant.

MYCTERIA, the JABIRU, a genus of birds belonging to the order of grallæ. The bill is long, bending upwards, and acute; the nostrils are small and linear; there is no tongue; and the feet have four toes. There are two species: 1. The Americana, or American jabiru, is about the size of a turkey. See Plate Nat. Hist. fig. 288. The bill is long, stout, and of a black colour; the whole plumage is white, except the head, and about two-thirds of the neck, which are bare of feathers and of a blackish colour; the remainder is also bare, and of a fine red; on the hind-head are a few greyish feathers; the legs are strong, of a great length, and covered with black scales; wings and tail even at the end. This bird is found in all the savannas of Cayenne, Guiana, and other parts of South America. It is migratory and gregarious. It makes its nest in great trees, which grow on the borders; lays two eggs, and brings up the young in the nest till they can descend to the ground. The colour of the young birds is grey; the second year it changes to rose-colour, and the third to pure white. They are very wild and voracious, and their food is fish, which they devour in great quantities. The flesh of the young birds is said to be good eating, but that of the old is hard and oily. 2. The Asiatica, or Indian jabiru, is of a large size. The bill is dusky, almost straight above, and gibbous near the forehead; the under mandible swelled beneath; and from the base of the bill there passes through and beyond the eye a black streak. The general colour of the plumage is white; the lower half of the back, the prime quills, and tail, are black; the legs a pale red. This species inhabits the East Indies, and feeds on snails.

MYGINDA, a genus of the tetragynia order, in the tetrandria class of plants; and in the natural method ranking with those of which the order is doubtful. The calyx is quadripartite; the petals four; the fruit a globose plum. There are three species, shrubs of the West Indies.

MYOSOTIS, *Scorpion-grass*, a genus of the monogynia order, in the pentandria class of plants; and in the natural method ranking under the 41st order, asperifoliæ. The corolla is salver-shaped, quinquefid, and emarginated; the throat shut up by small arches. There are seven species, of which the most remarkable is the scorpioides, or mouse-ear. This is a weed of Britain, growing naturally in dry fields, and margins of springs and rills. The blossoms vary from a full blue to a very pale one, and sometimes a yellow; and appear in a long spirally twisted spike. When it grows in the water, and its taste and smell are thereby rendered less observable, sheep will sometimes eat it; but it is generally fatal to them. Cows, horses, swine, and goats, refuse it.

MYOSURUS, a genus of the polyginia order, in the pentandria class of plants; and in the natural method ranking under the 26th order, multisiliquæ. The calyx is pentaphyllous, the leaves cohering at the base; there are five subulated nectaria resembling petals; the seeds are numerous. There is one species, a weed.

MYOXUS, *dormouse*, a genus of quadrupeds of the order glires: The generic character is, front-teeth two, the upper cuneated, the lower compressed; grinders four in each jaw; vibrissæ long; tail cylindric, villose, thicker towards the end; legs of equal length, fore-feet tetradactylous.

1. Myoxus glis, fat dormouse; this species, the glis of Pliny and the old naturalists, is a native of France and the South of Europe. It also occurs in Russia, Austria, &c. residing on trees, and leaping from bough to bough in the manner of a squirrel, though with a less degree of agility. It feeds on nuts, acorns, fruit, &c. and during great part of the winter remains torpid in its nest, which is prepared in the hollows of trees, with dried leaves, moss, &c. During its state of torpidity, it is said to grow very fat, contrary to the nature of most of the hybernating or sleeping animals; which are observed, on their first emerging from that state, to be far leaner than before its commencement. It is probable, however, that this animal awakes at intervals, and indulges in the use of its collected stores of provision.

It is but just to observe, that the count de Buffon has very properly exposed the absurdity of the ancient notion; and has observed that the animal occasionally wakess and makes use of its stock of provision. The truth is, that it is at all times fat, and appear, as much so in spring as in autumn. By the ancient Romans it was numbered among the articles of luxury, and was fattened in proper receptacles, called gliraria.

The size of this elegant species is not very far short of that of a squirrel, measuring from nose to tail near six inches, and the tail four and a half. It is an animal of a much thicker form, in proportion, than a squirrel, and is of an elegant ash-colour, white on the under parts and insides of the limbs; the tail is very villose or furry, and of a slightly spreading form, like that of a squirrel; the eyes are large and black; the ears thin, rounded, and very slightly haired. Sometimes the upper parts of the body have a slight dusky, and sometimes a ferruginous tinge. Its general manners resemble those of a squirrel, but it is not easily tamed. The young are produced about the middle of summer, and are four or five in number.

2. Myoxus nitella, garden dormouse. The garden dormouse is a native of the temperate and warmer regions of Europe and Asia, and is commonly found in gardens, feeding on various kinds of fruit, particularly peaches and apricots. It makes its nest, like the rest of this genus, in the hollows of trees, and sometimes in those of walls, or even in the ground about the roots of trees, &c. collecting, for this purpose, dried leaves, grass, mosses, &c. In autumn it collects a quantity of nuts, mast, &c. and deposits it in its hole; and during the greatest part of the winter remains in a state of torpidity, awaking only at distant intervals. Its general length is about four inches and a half, and the tail rather less. It is of an elegant rufous or ferruginous colour above, and yellowish white beneath; the eyes are imbedded in a large black patch or spot, which extends to some distance beyond each ear; the tail is somewhat wider towards the end, and sharpens at the extremity, and is marked on that part by a longitudinal black stripe, having the edges white. These animals produce their young about the middle of summer, which are about five or six in number, and are said to be of a very quick growth.

3. Myoxus muscardinus, common dormouse. The size of this animal is nearly equal to that of a mouse, but it is of a more plump or rounded form, and the nose is more obtuse in proportion; the eyes are large, black, and prominent; the ears broad, thin, and semitransparent; the fore-feet have four toes, and the hind-feet five, but the interior of these latter are destitute of nails; the tail is about two inches and a half long, and is closely covered on all sides with hair, which is rather longer towards the tip than on the other parts; the head, back, sides, belly, and tail, are of a tawny-red colour; the throat white; the fur is remarkably soft, and the whole animal has a considerable degree of elegance in its appearance. It sometimes happens that the colour is rather brown than reddish.

Dormice, says Mr. Pennant, inhabit woods or very thick hedges; forming their nests in the hollows of some low tree, or near the bottom of a close shrub. As they want much of the sprightliness of the squirrel, they never aspire to the tops of trees, or attempt to bound from spray to spray. Like the squirrel, they form little magazines of nuts, &c. for their winter provision, and take their food in the same upright posture. The consumption of their hoard during the rigour of winter is but small, for they sleep most part of the time, retiring into their holes on the approach of winter, and rolling themselves up, lie torpid during the greatest part of the gloomy season. Sometimes they experience a short revival in a warm sunny day; when they take a little food, and then relapse into their former state.

These animals seldom appear far from their retreats, or in any exposed situation; for which reason they seem less common in this country than they really are. They make their nest of grass, moss, and dead leaves. According to the count de Buffon, it consists of interwoven herbs, and is six inches in diameter, open only above, and is situated between the branches of hazel and brushwood. The number of young is generally three or four.

MYRICA, *Gale*, or *Sweet-willow*, a genus of the tetrandria order, in the diœcia class of plants; and in the natural method ranking under the 5th order, amentaceæ. The scale of the male catkin is in the form of a crescent, without any corolla. The scale of the female catkin the same: there is no corolla; but two styles, and a monospermous berry.

1. The gale, Dutch myrtle, or sweet-willow, grows naturally upon bogs in many places both of Scotland and England. It rises about four feet high. The female flowers or catkins are produced from the sides of the branches, growing upon separate plants from the male, which are succeeded by clusters of small berries, each having a small seed. It flowers in July, and ripens in autumn. When transplanted into shrubberies, the moistest parts must be assigned to it.

The leaves, flowers, and seeds of this plant, have a strong fragrant smell, and a bitter taste. They are said to be used among the common people for destroying moths and cutaneous insects, being accounted an enemy to insects of every kind; internally, in infusions, as a stomachic and vermifuge; and as a substitute to hops for preserving malt liquors, which they render more inebriating, and of consequence less salubrious; it is said that this quality is destroyed by boiling.

2. The cerifera, wax-bearing myrica, or candleberry myrtle, is a native of North America. It is a small tree, about 10 or 12 feet high, with crooked stems branching forth near the ground irregularly. The leaves grow irregularly on them all round; sometimes by pairs, sometimes alternately, but generally at unequal distances. The branches of the old plants shed their leaves in the autumn; but the young plants raised from seeds retain them the greatest part of the winter, so as during that season to have the appearance of an evergreen. But this beauty will not be lasting, for they shed their leaves proportionably earlier as the plants get older. There are both male and female trees of this sort: the flowers are small, of a whitish colour, and make no figure; neither does the fruit that succeeds the female (which is a small, dry, blue berry), though produced in clusters, make any shew: so that it is from the leaves this tree receives its beauty and value; for these being bruised, as well as the bark of the young shoots, emit the most refreshing and delightful fragrance, that is exceeded by no myrtle, or any other aromatic shrub. See Plate Nat. Hist. fig. 289.

There is a variety of this species of lower growth, with shorter but broader leaves, and of equal fragrance. This grows commonly in Carolina; where the inhabitants collect from its berries a wax of which they make candles, and which occasions its being called the candleberry tree. It delights in a moistish soil. The wax is procured in the following manner: In November and December, when the berries are ripe, a man with his family will remove from home to some island or sand-bank near the sea, where these trees most abound, taking with them kettles to boil the berries in. He builds a hut with palmetto-leaves for the shelter of himself and family during his residence there, which is commonly four or five weeks. The man cuts down the trees, while the children strip off the berries into a porridge-pot; and having put water to them, they boil them till the oil floats, which is then skimmed off into another vessel. This is repeated till no more oil appears. When cold, this hardens to the consistence of wax, and is of a dirty-green colour. They then boil it again, and clarify it in brass kettles; which gives it a transparent greenness. These candles burn a long time, and yield a grateful smell. They usually add a fourth part of tallow, which makes them burn clearer. There are seven other species.

MYRIOPHYLLUM, a genus of the polyandria order, in the monœcia class of plants; and in the natural method ranking under the 15th order, inundatæ. The male calyx is tetraphyllous; there is no corolla; the stamina are eight in number. The female calyx is tetraphyllous; the pistils four; there is no stile; and four naked seeds. There are two species, aquatics of Europe.

MYRISTICA, the nutmeg-tree; in botany, a genus of plants belonging to the class diœcia, and order syngenesia, and of the natural order lauri. The male calyx is monophyllous, strong, and parted into three laciniæ of an oval shape, and ending in a point: it has no corolla. In the middle of the receptacle rises a column of the height of the calyx; to the upper part of which the antheræ are attached. They vary in number from three to twelve or thirteen. The female calyx and corolla, as in the male, on a distinct tree. The germen of an oval shape; the style short, with a bifid stigma, the laciniæ of which are oval and spreading. The fruit is of that sort called drupa. It is fleshy, roundish, sometimes unilocular, sometimes bivalved, and when ripe bursts at the side. The seed is enveloped with a fleshy and fatty membraneous substance, which divides into filaments: this, in one of the species is the mace of the shops. The seed or nutmeg is round or oval-shaped, unilocular, and contains a small kernel, variegated on the surface by the fibres running in the form of a screw.

There are five species of this genus according to some authors; but several of these being only varieties, may be reduced to three, viz. 1. Myristica fatua, or wild nutmeg; this grows in Tobago, and rises to the height of an apple-tree; has oblong, lanceolated, downy leaves, and hairy fruit; the nutmeg of which is aromatic, but when given inwardly is narcotic, and occasions drunkenness, delirium, and madness for a time. 2. The myristica sebifera, a tree frequent in Guiana, rising to 40 or even to 60 feet high; on wounding the trunk of which, a thick, acrid, red juice runs out. Aublet says nothing of the nutmegs being aromatic; he only observes, that a yellow fat is obtained from them, which serves many economical and medical purposes, and that the natives make candles of it. 3. The mysteria aromatica, or nutmeg, attains the height of 30 feet, producing numerous branches, which rise together in stories, and covered with bark, which of the trunk is a reddish brown, but that of the young branches is of a bright green colour; the leaves are nearly elliptical, pointed, undulated, obliquely nerved, on the upper side of a bright green, on the under whitish, and stand alternately upon footstalks; the flowers are small, and hang upon slender peduncles, proceeding from the axillæ of the leaves: they are both male and female upon separate trees.

The nutmeg has been supposed to be the comacum of Theophrastus, but there seems little foundation for this opinion; nor can it with more probability be thought to be the chrysobalanos of Galen. Our first knowledge of it was evidently derived from the Arabians; by Avicenna it was called jiausiban, or jausiband, which signifies nut of Banda.

There are two kinds of nutmegs, the one male and the other female. The female is that in common use; the male is longer and more cylindric, but it has less of the fine aromatic flavour than the other. This is very subject to be worm-eaten, and by the Dutch it is strictly prohibited from being packed with the others, because it will give occasion to their being worm-eaten too, by the insects getting from one species to the other. An almost exclusive and very lucrative trade in nutmegs from the island of Ceylon was carried on by the Dutch, but it is now transferred to the English, who have become masters of the colony.

The seeds or kernels called nutmegs are well known, as they have been long used both for culinary and medical purposes. Distilled with water, they yield a large quantity of essential oil, resembling in flavour the spice itself; after the distillation, an insipid sebaceous matter is found swimming on the water; the decoction inspissated, gives an extract of an unctuous, very lightly bitterish taste, and with little or no astringency. Rectified spirit extracts the whole virtue of nutmegs by infusion, but elevates very little of it in distillation; hence the spirituous extract possesses the flavour of the spice in an eminent degree.

Nutmegs, when heated, yield to the press a considerable quantity of limpid yellow oil, which on cooling concretes into a sebaceous consistence. In the shops we meet with three sorts of unctuous substances, called oil of mace, though really expressed from the nutmeg. The best is brought from the East Indies in stone jars; this is of a thick consistence, of the colour of mace, and has an agreeable fragrant smell; the second sort, which is paler-coloured, and much inferior in quality, comes from Holland in solid masses, generally flat, and of a square figure: the third, which is the worst of all, and usually called common oil of mace, is an artificial composition of sevum, palm oil, and the like, flavoured with a little genuine oil of nutmeg.

Method of gathering and preparing nutmegs.—When the fruit is ripe, the natives ascend the trees, and gather it by pulling the branches to them with long hooks. Some are employed in opening them immediately, and in taking off the green shell or first rind, which is laid together in a heap in the woods, where in time it putrefies. As soon as the putrefaction has taken place, there spring up a kind of mushrooms, called boleti moschatyni, of a blackish colour, and much valued by the natives, who consider them as delicate eating. When the nuts are stripped of their first rind, they are carried home, and the mace is carefully taken off with a small knife. The mace, which is of a beautiful red, but afterwards assumes a darkish red colour, is laid to dry in the sun for the space of a day, and is then removed to a place less exposed to his rays, where it remains for eight days that it may soften a little. They afterwards moisten it with sea-water, to prevent it from drying too much, or from losing its oil. They are careful, however, not to employ too much water, lest it should become putrid, and be devoured by the worms. It is last of all put into small bags, and squeezed very close.

The nuts, which are still covered with their ligneous shell, are for three days exposed to the sun, and afterwards dried before a fire, till they emit a sound, when they are shaken; they then beat them with small sticks in order to remove their shell, which flies off in pieces. These nuts are distributed into three parcels; the first of which contains the largest and most beautiful, which are destined to be brought to Europe; the second contains such as are reserved for the use of the inhabitants; and the third contains the smallest, which are irregular or unripe. These are burnt; and part of the rest is employed for procuring oil by pressure. A pound of them commonly gives three ounces of oil, which has the consistence of tallow, and has entirely the taste of nutmeg. Both the nut and mace, when distilled, afford an essential, transparent, and volatile oil, of an excellent flavour.

The nutmegs which have been thus selected, would soon corrupt if they were not watered, or rather pickled, with lime-water made from calcined shell-fish, which they dilute with salt water till it attains the consistence of fluid pap. Into this mixture they plunge the nutmegs, contained in small baskets, two or three times, till they are completely covered over with the liquor. They are afterwards laid in a heap, where they heat, and lose their superfluous moisture by evaporation. When they have sweated sufficiently, they are then properly prepared, and fit for a sea-voyage.

The medicinal qualities of nutmeg are supposed to be aromatic, anodyne, stomachic, and astringent; and with a view to the last mentioned effects, it has been much used in diarrhœas and dysenteries. To many people the aromatic flavour of nutmeg is very agreeable; they however should be cautious not to use it in large quantities, as it is apt to affect the head, and even to manifest an hypnotic power in such a degree as to prove extremely dangerous. Bontius speaks of this as a frequent occurrence in India; and Dr. Cullen relates a remarkable instance of this soporific effect of the nutmeg, which fell under his own observation, and hence concludes, that in apoplectic and paralytic cases this spice may be very improper. He observes that a person by mistake took two drams or a little more of powdered nutmeg; he felt it warm in his stomach, without any uneasiness; but in about an hour after he had taken it he was seized with a drowsiness, which gradually increased to a complete stupor and insensibility; and not long after he was found fallen from his chair, lying on the floor of his chamber in the state mentioned. Being laid abed he fell asleep; but waking a little from time to time, he was quite delirious; and he thus continued alternately sleeping and delirious for several hours. By degrees, however, both these symptoms diminished; so that in about six hours from the time of taking the nutmeg he was pretty well recovered from both. Although he still complained of head-ache, and some drowsiness, he slept naturally and quietly the following night, and next day was quite in his ordinary health.

The officinal preparations of nutmeg are, a spirit and essential oil; and the nutmeg in substance roasted, to render it more astringent. Both the spice itself and its essential oil enter several compositions, as the confectio aromatica, spiritus ammoniæ, com.,&c. Mace possesses qualities similar to those of the nutmeg, but is less astringent, and its oil is supposed to be more volatile and acrid.

MYRMECIA, a genus of the class and order tetrandria monogynia; the calyx is tubular, five-toothed; cor. one-petalled; germ five glands at the base; stigma bilamelate; caps. two-valved. There is one species, a shrub of Guiana.

MYRMECOPHAGA, Ant-eater, a genus of quadrupeds of the order bruta. The generic character is, teeth none; tongue cylindric, extensile; mouth lengthened into a somewhat tubular form; body covered with hair. The animals of this genus live entirely on insects, more particularly on the various kinds of ants; in order to obtain which, they extend their tongue, which is of a very great length, and of a roundish or worm-like form, into the nests of those insects; and when, by means of the viscid moisture with which it is covered, a sufficient number are secured, they retract it suddenly into the mouth, and swallow them. A part of the generic character of the myrmecophaga is the total want of teeth, in which particularity it resembles no other animals except those of the genus manis, in which the same circumstance takes place. There are, however, in the ant-eaters, according to the observations of Mons. Broussonet, certain bones or processes not unlike teeth, situated deep at the entrance of the gullet or œsophagus; or rather, according to the celebrated Camper, at the lower end of the jaws. The species of ant-eaters are not numerous.

1. Myrmecophaga jubata, great ant-eater. This is by far the largest of the ant-eaters, being upwards of seven feet in length, from the tip of the nose to the end of the tail; but if measured to the origin of the tail, it is no more than about five feet and a half. It is an animal of an uncouth appearance; the head is small; the snout very long; the eyes small; the ears short and round; the shoulders thick and muscular, from whence the body tapers towards the tail; but the thighs are thick and stout; the colour of the animal is a deep grey, with a very broad band of black running from the neck downwards on each side the body, growing gradually narrower as it passes down; this black band is accompanied on the upper part by a streak of white; the fore legs are of a lighter cast than the hinder; and have a patch or spot of black in front not much above the foot; the tail is black, extremely long and bushy; the hair on the whole body, but especially on the tail, is very harsh and coarse: there are four toes on the fore-feet, and five on the hind: the two middle claws of the fore feet are extremely large and strong; which render this creature, though destitute of teeth, a very formidable adversary; since it has been known to destroy animals of much greater apparent strength than itself; fixing its claws upon them, and exerting such powerful strength as to kill them by continued laceration and pressure. It is a native of Brasil and Guiana; it is chiefly a nocturnal animal, and is said to sleep during the greatest part of the day in retired places. Its pace is somewhat slow, and its manners dull and heavy. It is said to swim with ease; at which time it flings its tail over its back. A living specimen was some years ago brought into Spain, and kept in the royal menagerie at Madrid; in this state of confinement it would readily eat raw meat cut small, and was said to swallow four or five pounds in a day. Its length was six feet, from the nose to the end of the tail, and its height was two feet.

2. Myrmecophaga didactyla, little ant-eater. This is an animal of great elegance. It is not superior in size to a squirrel; measuring little more than seven inches from the nose to the tail, which is longer than the body and head: the head is small; the snout sharpened, and slightly bent downwards; the legs are short; the fore feet have only two claws on each, the exterior one much larger and stronger than the interior; on each of the hind feet are four claws of moderate size; the ears are very small, and hid in the fur; the eyes are also small. The whole animal is covered with a beautiful soft, and somewhat crisped or curled fur, of a pale yellow colour, or rather yellow-brown; the tail, which is very thick at the beginning or base, gradually tapers to the tip; and the lower surface, for about the space of four inches from the tip, is bare; the tail in this species being prehensile, and the animal commonly residing on trees, and preying on ants, by means of its long tongue, in the manner of other species. It is a native of Guiana. See Plate Nat. Hist. fig. 290.

3. Myrmecophaga aculeata, aculeated ant-eater. The aculeated ant-eater is one of those curious animals which have been lately discovered in the vast island, or rather continent, of Australasia or New Holland; and is a striking instance of that beautiful gradation, so frequently observed in the animal kingdom, by which creatures of one tribe or genus approach to those of a very different one. It forms a connecting link between the very distant Linnæan genera of hystrix (porcupine) and myrmecophaga (ant-eater), having the external coating and general appearance of the one, with the mouth and peculiar generic characters of the other. This animal, so far as may be judged from the specimens hitherto imported, is about a foot in length.

In its mode of life this animal resembles the rest of the ant-eaters, being generally found in the midst of some large ant-hill: it burrows with great strength and celerity under ground, when disturbed; its feet and legs being most excessively strong and short, and wonderfully adapted to this purpose. It will even burrow under a pretty strong pavement, removing the stones with its claws; or under the bottom of a wall. During these exertions, its body is strengthened or lengthened to an uncommon degree, and appears very different from the short or plump aspect which it bears in its undisturbed state.

It cannot escape the observation of every scientific naturalist, that, in consequence of the discovery of this curious animal, the Linnæan character of myrmecophaga is, in part, rendered inapplicable. Since, therefore, the genera of manis and myrmecophaga differ only in the external covering (the former being coated with scales, and the latter with hair), it would, perhaps, be not improper to conjoin the two genera, to add this as a new species, and to give as part of the generic character, corpus pilis, squamis, vel aculeis tectum. Or it might even constitute a new genus, which would differ from those of manis and myrmecophaga, in having the body covered with spines.

MYRMELEON, a genus of insects of the order neuroptera: the generic character is, mouth furnished with jaws, teeth two; feelers four, elongated; stemmata none; antennæ clavated, of the length of the thorax; wings deflected; tail of the male furnished with a forceps consisting of two straightish filaments. Of this genus the species whose history is best understood is the myrmeleon formicaleo of Linnæus, whose larva has long been celebrated by naturalists for its wonderful ingenuity, in preparing a kind of pitfal or deceptive cavity for the destruction of such insects as happen unwarily to enter it. The myrmeleon formicaleo, in its complete or fly state, bears no inconsiderable resemblance to a small dragon-fly, from which, however, it may readily be distinguished by its antennæ. It is of a predacious nature, flying chiefly by night, and pursuing the smaller insects in the manner of a libellula. It deposits its eggs in dry sandy situations; and the young larvæ, when hatched, begin separately to exercise their talent of preparing, by turning themselves rapidly round, a very small conical cavity in the sand. Under the centre of the cavity the little animal conceals itself, suddenly rushing forth at intervals in order to seize any small insect which, by approaching the edge of the cavity, has been so unfortunate as to fall in; and after sucking out its juices through its tubular forceps, throws it by a sudden exertion to some distance from the cavity. As the creature increases in size it enlarges the cavity, which at length becomes about two inches or more in diameter. The larva, when full-grown, is more than half an inch long, and is of a flattened figure, broad towards the upper part, and gradually tapering to an obtuse point at the extremity. It is of a brown colour, and beset with numerous tufts of dusky hair, which are particularly conspicuous on each side the annuli of the abdomen; the legs are slender; the head and thorax rather small; the tubular jaws long, curved, serrated internally, and very sharp-pointed. The whole animal is of an unpleasing aspect, and on a cursory view bears a general resemblance to a flat-bodied spider. When magnified, its appearance is highly uncouth.

The ingenious Reaumur and Roësel have given accurate descriptions of this larva and its extraordinary history. It is one of those whose term of life, like that of the libellulæ and ephemeræ, is protracted to a very considerable space, since it survives the first winter in its larva state, taking no nourishment during that time, and in the spring resumes its usual manner of preying. In preparing its pit, it begins by tracing an exterior circle of the intended diameter of the cavity, continuing its motion, in a spiral line, till it gets to the centre, thus marking several volutes in the sand, resembling the impression of a large helix or snail-shell; and after having sufficiently deepened the cavity by a repetition of this motion, it smooths the sides into a regular shape by throwing out the superfluous sand lying on the ridges; this it does by closing its forceps in such a manner, that together with the head, they form a convenient shovel, with which it throws the sand with so strong a motion out of the cavity, that the grains often fall to the distance of near a foot beyond the brink. The depth of the pit is generally equal to the diameter. When full-grown and ready to change into a chrysalis, the animal envelopes itself in a round ball of sand, agglutinated and connected by very fine silk, which it draws from a tubular process at the extremity of the body; with this silk it also lines the internal surface of the ball, which, if opened, appears coated by a fine pearl-coloured silken tissue. It continues in the state of chrysalis about four weeks, and then gives birth to the complete insect.

The myrmeleon barbarus has antennæ as long as the body; thorax spotted with yellow. See Plate Nat. Hist. fig. 291.

MYROBALANS, a kind of medicinal fruit brought from the Indies. See MATERIA MEDICA.

MYRODENDRUM, a genus of the class and order polyandria monogynia. The cor. is five-petalled; stigma, capitate, five-lobed; per. five-celled. There is one species, a tree of Guiana.

MYRODIA, a genus of the monadelphia polyandria class and order; the calyx is single, one-leafed; cor. five-petalled; pist. one column of anthers undivided, drupe dry, two nuts. There are two species, shrubs of the West Indies.

MYROSMA, a genus of the monandria monogynia class and order; the cal. is double, outer three-leaved, inner three-parted; cor. five-parted: caps. three-cornered. There is one species, a shrub of Surinam.

MYROXYLUM, a genus of the monogynia order, in the decandria class of plants. The calyx is campanulated; the superior petal larger than the rest; the germ. is longer than the corolla; the legumen monospermous. There is but one species, the peruiferum, a native of Peru and the warmer parts of Africa. It is this shrub that yields the balsam of Peru, which is said to be extracted from it by coction in water. This balsam, as brought to us, is nearly of the consistence of thin honey, of a reddish brown colour inclining to black, an agreeable aromatic smell, and a very hot biting taste. Distilled with water, it yields a small quantity of a fragrant essential oil of a reddish colour; and in a strong fire, without addition, a yellowish red oil. Balsam of Peru is a very warm aromatic medicine, considerably hotter and more acrid than copaiva. (See BALSAM.) Its principal effects are to warm the habit, to strengthen the nervous system, and attenuate viscid humours. Hence its use in some kinds of asthmas, gonorrhœas, dysenteries, and other disorders proceeding from a debility of the solids, or sluggishness and inactivity of the juices. It is also employed externally, for cleansing and healing wounds and ulcers, and sometimes against palsies and rheumatic pains. There is another sort of balsam of Peru of a white colour, and considerably more fragrant than the former. This is very rarely brought to us. It is said to be the produce of the same plant which yields the common or black balsam; and to exsude from incisions made in the trunk, while the former is obtained by boiling. There is also a third kind, commonly called the red or dry. This is supposed to obtain a different state from the white, merely in consequence of the treatment to which it is subjected after it is got from the tree. It is almost as fragrant as the balsam of Gilead, held in so high esteem among the Eastern nations. It is very rarely in use in Britain, and almost never to be met with in our shops.

MYRRH, a gummy resinous concrete juice. The plant from which this substance is obtained, is not certainly known. According to Bruce, it belongs to the genus mimosa, and grows in Abyssinia and Arabia. It is in the form of tears. Colour reddish-yellow, sometimes transparent, but more frequently opaque. Taste brittle and aromatic. Does not melt when heated, and burns with difficulty. With water it forms a yellow solution. The solution in alcohol becomes opaque when mixed with water. By distillation it yields oil. Its specific gravity is 1.36. It is employed in medicine, and is soluble in alkalies.

The medical effects of this aromatic bitter are, to warm and strengthen the viscera; it frequently occasions a mild diaphoresis, and promotes the fluid secretions in general. Hence it proves serviceable in languid cases, diseases arising from a simple inactivity, cachectic disorders, and where the lungs and thorax are oppressed by viscid phlegm.

Rectified spirit extracts the fine aromatic flavour and bitterness of this drug, and does not elevate any thing of either in evaporation; the gummy substance left by this menstruum has a disagreeable taste, with scarcely any of the peculiar flavour of the myrrh; this part dissolves in water, except some impurities which remain. In distillation with water, a considerable quantity of a ponderous essential oil arises, resembling in flavour the original drug. Myrrh is the basis of an officinal tincture. It enters the pilulæ ex aloe et myrrha, the pilulæ e gummi, the pilulæ stomachicæ, and other formulæ.

MYRSINE, a genus of the monogynia order, in the pentandria class of plants, and in the natural method ranking under the 18th order, bicornes. The corolla is semiquinquefid and connivent; the germen filling the corolla; the berry quinquelocular and pentaspermous. There are two species, herbs of the Cape.

MYRTLE. See MYRTUS.

MYRTUS, the myrtle; a genus of the monogynia order, in the icosandria class of plants; and in the natural method ranking under the 19th order, hesperidæ. The calyx is quinquefid, superior; there are five petals; the berry is dispermous or trispermous. There are 36 species, of which the most remarkable are:

1. The communis, or common myrtle-tree, of which the most material varieties are: broad-leaved Roman myrtle, with oval, shining, green leaves, an inch and a half long, and one broad; and which is remarkably floriferous. Gold-striped broad-leaved Roman myrtle. Broad-leaved Dutch myrtle, with spear-shaped, sharp-pointed, dark-green leaves, an inch long, and about three quarters of one broad. Double-flowered Dutch myrtle. Broad-leaved Jew's myrtle, having the leaves placed by threes at each joint; by which particular circumstance this species is in universal estimation among the Jews in their religious ceremonies, particularly in decorating their tabernacles; and for which purpose many gardeners about London cultivate this variety with particular care to sell to the above people: for the true sort, having the leaves exactly by threes, is very scarce, and is a curiosity; but by care in its propagation, taking only the perfectly ternate-leaved shoots for cuttings, it may be increased fast enough; and is worth the attention of the curious, and particularly those who raise myrtles for the London markets. Orange-leaved Spanish myrtle, with oval spear-shaped leaves, an inch and a half long or more, and one broad, in clusters round the branches, and resembling the shape and colour of orange-tree leaves. Gold-striped-leaved orange myrtle. Common upright Italian myrtle, with its branches and leaves growing more erect, the leaves oval, lanceolate-shaped, acute-pointed, and near an inch long and half one broad. Silver-striped upright Italian myrtle. White-berried upright Italian myrtle. Portugal acute-leaved myrtle, with spear-shaped, oval, acute-pointed leaves, about an inch long. Box-leaved myrtle, with weak branches, and small, oval, obtuse, lucid-green, closely-placed leaves. Striped box-leaved myrtle. Rosemary-leaved myrtle. Silver-striped rosemary-leaved myrtle. Thyme-leaved myrtle, with very small closely-placed leaves. Nutmeg-myrtle, with erect branches and leaves; the leaves oval, acute-pointed, and finely scented like a nutmeg. Broad-leaved nutmeg-myrtle. Silver-striped-leaved ditto. Cristated or cock's-comb myrtle, frequently called bird's-nest myrtle. These are all beautiful evergreen shrubs, of exceeding fragrance, exotics originally of the southern parts of Europe, and of Asia and Africa, and consequently in this country require a shelter of a greenhouse in winter.

2. The pimenta, pimento, Jamaica pepper, or allspice tree, grows about 30 feet in height and two in circumference; the branches near the top are much divided and thickly beset with leaves, which by their continual verdure always give the tree a beautiful appearance; the bark is very smooth externally, and of a grey colour; the leaves vary in shape and in size, but are commonly about four inches long, veined, pointed, elliptical, and of a deep shining green colour; the flowers are produced in bunches or panicles, and stand upon subdividing or trichotomous stalks, which usually terminate the branches; the calyx is cut into four roundish segments; the petals are also four, white, small, reflex, oval, and placed opposite to each other between the segments of the calyx; the filaments are numerous, longer than the petals, spreading, of a greenish-white colour, and rise from the calyx and upper part of the germen; the antheræ are roundish, and of a pale yellow colour; the style is smooth, simple, and erect; the stigma is obtuse; the germen becomes a round succulent berry, containing two kidney-shaped flattish seeds. This tree is a native of New Spain and the West India islands. In Jamaica it grows very plentifully; and in June, July, and August, puts forth its flowers, which, with every part of the tree, breathe an aromatic fragrance. The berries when ripe are of a dark purple colour, and full of a sweet pulp, which the birds devour greedily. The pimento is a most beautiful odoriferous evergreen, and exhibits a fine variety in the stove at all seasons.

MYTILUS, the *mussel*, a genus of animals belonging to the order of vermes testacei. The animal is an ascidia; the shell bivalve, often affixed to some substance by a beard; the hinge without a tooth, marked by a longitudinal hollow line. Of these animals there are a great many species, some of them inhabiting the seas, others the rivers and ponds. Several of them are remarkable for the beauty of their internal shell, and for the pearls which are sometimes found in them.

1. The edulis, or edible mussel, has a strong shell, slightly incurvated on one side, and angulated on the other. The end near the hinge is pointed, the other rounded. When the epidermis is taken off it is of a deep-blue colour. It is found in immense beds, both in deep water and above low-water mark. This species inhabits the European and Indian seas. Between the tropics it is largest, and smaller within the polar circle. It is said to be hurtful if too often eaten, or in too great quantities.

2. The anatinus, or duck mussel, has a shell more oblong and less convex than the last; is very brittle and semitransparent; the space round the hinges like the last; the length about five inches, breadth two. It is found in Europe in fresh waters. Both it and the cygneus are devoured by swans and ducks, whence their names: crows also feed on these mussels, as well as on different other shell-fish; and it is diverting to observe, that when the shell is too hard for their bills they fly with it to a great height, drop the shell on a rock, and pick out the meat when the shell is fractured by the fall.

3. The violacea, or violet mussel, has the shell longitudinally furrowed, the rim very obtuse, somewhat formed like the mytilus edulis, but considerably larger and more flattened, of a beautiful violet-colour. Inhabits the southern ocean.

4. The margarite ferus produces the true mother-of-pearl, and frequently the most valuable pearls: the outside sometimes sea-green, or chesnut, or bloom-colour with white rays; when the outer coat is removed it has the same lustre as the inside: the younger shells have ears as long as the shell, and resemble scallops.

There are between 50 and 60 other species.

Mussels not only open and shut their shells at pleasure, but they have also a progressive motion; they can fasten themselves where they please; they respire water like the fishes; and some even flutter about on its surface so as to inhale air. If they lie in shallow places a small circular motion is seen above the heel of the shell, and a few moments after they cast out the water by one single stroke at the other end of the shell. The mouth is situated near the sharp angle of the animal; and is furnished with four floating fringes in the shape of mustachios, which may perhaps answer the purpose of lips. The barbs which surround the edge of almost half the mussel, are a wonderful web of hollow fibres which serve as fins or organs of respiration, as vessels for the circulation of the fluids; and probably, as some philosophers suppose, as wedges for opening their shells; for we observe two large muscles or tendons for the purpose of shutting them; but we in vain look for their antagonists, or those which are destined to open them. When the mussel wishes to open itself, it relaxes the two muscles or tendons, and swells the fringes, which act as wedges, and separate the shells. The animal shuts up itself by the contraction of two thick fibrous muscles, which are fixed internally to each end of the shells; and these shells are lined all round with a membrane or epidermis, which unites them so closely together when they are soaked in water, that not the smallest drop can escape from the mussel. When mussels choose to walk they often contrive to raise themselves on the sharp edge of their shells, and put forth a fleshy substance susceptible of extension, which serves them as a leg to drag themselves along, in a kind of groove or furrow which they form in the sand or mud, and which supports the shell on both sides. In ponds these furrows are very observable. From the same member or leg hang the threads by which the animals fasten themselves to rocks, or to one another.

According to the observations of M. Mery, of the Paris academy, and the subsequent experiments of other naturalists, mussels are all androgynous; and, from a peculiar generative organization, each individual is of itself capable of propagating its species, and annually does it without the intercourse of any other. This is altogether singular, and different from what takes place in snails, earthworms, and other androgenous or hermaphroditical animals. In the spring, mussels lay their eggs; there being none found in them but in winter. The minute eggs, or embryos, are by the parent placed in due order, and in a very close arrangement, on the outside of the shell; where, by means of a gluey matter, they adhere very fast, and continually increase in size and strength, till becoming perfect mussels, they fall off and shift for themselves, leaving the holes where they were placed behind them. This abundance the mussel-shells very plainly show, when examined by the microscope, and sometimes the number is 2000 or 3000 on one shell; but it is not certain that these have been all fixed there by the mussel within;

for these fish usually lying in great numbers near one another, the embryos of one are often affixed to the shell of another. The fringed edge of the mussel, which Lewenhoeck calls the beard, has in every the minutest part of it such variety of motions as is inconceivable; for being composed of longish fibres, each fibre has on both sides a vast many moving particles.

The mussel is infested by several enemies in its own element; according to Reaumur it is in particular the prey of a small shell-fish of the trochus kind. This animal attaches itself to the shell of the mussel, pierces it with a round hole, and introduces a sort of tube, five or six lines long, which it turns in a spiral direction, and with which it sucks the substance of the mussel. Mussels are also subject to certain diseases, which have been supposed to be the cause of those bad effects which sometimes happen from the eating of them.

MYXINE, the hag; a genus of insects belonging to the order of vermes intestini. It has a slender body, carinated beneath; mouth at the extremity, cirrated; the two jaws pinnated; an adipose or rayless fin round the tail and under the belly. The only remarkable species is the glutinosa, about eight inches long. It inhabits the ocean; enters the mouths of fish when on the hooks of lines that remain a tide under water; and totally devours the whole, except the skin and bones. The Scarborough fishermen often take it in the robbed fish, on drawing up their lines. Linnæus attributes to it the property of turning water into gube.

N

N, or n, the thirteenth letter of our alphabet; as a numeral stands for 900; and with a dash over it, thus N̄, for 900,000. N, or N°, stands for numero, *i. e.* in number; and N. B. for nota bene, note well, or observe well. Among the antient Romans, N. denotes Nepos, Nonnius, &c. N. C. Nero Cæsar, or Nero Claudius; N. L. Non liquet; N. P. Notarius Publicus; and NBL. stands for nobilis.

NADIR, in astronomy, that point of the heavens which is diametrically opposite to the zenith, or point directly over our heads.

NAIAS: a genus of the monandria order, in the diœcia class of plants; and in the natural method ranking with those of which the order is doubtful. The male calyx is cylindrical and bifid; the corolla quadrifid; there is no filament, nor is there any female calyx or corolla; there is one pistil, and the capsule is ovate and unilocular. There is one species, an aquatic of the South of Europe.

NAIL, *unguis.* See Anatomy, and Horn.

NAILS, in building, &c. small spikes of iron, brass, &c. which being driven into wood, serve to bind several pieces together, or to fasten something upon them. The several sorts of nails are very numerous: as, 1. back and bottom nails, which are made with flat shanks to hold fast, and not open the wood. 2. Clamp-nails, for fastening the clamps in buildings, &c. 3. Clasp-nails, whose heads clasping and sticking into the wood, render the work smooth, so as to admit a plane over it. 4. Clench-nails, used by boat- and barge-builders, and proper for any boarded-buildings that are to be taken down; because they will drive without splitting the wood, and draw without breaking; of this there are many sorts. 5. Clout-nails, used for nailing on clouts to axle-trees. 6. Deck-nails, for fastening of decks in ships, doubling of shipping, and floors laid with planks. 7. Dog-nails, for fastening hinges on doors, &c. 8. Flat-points, much used in shipping, and proper where there is occasion to draw and hold fast, and no conveniency of clenching. 9. Jobent-nails, for nailing thin plates of iron to wood, as small hinges on cupboard-doors, &c. 10. Lead-nails, for nailing lead, leather, and canvas, to hard wood. 11. Port-nails, for nailing hinges to the ports of ships. 12. Pound-nails, which are four square, and are much used in Essex, Norfolk, and Suffolk, and scarcely any where else, except for pailing. 13. Ribbing-nails, principally used in ship-building, for fastening the ribs of ships in their places. 14. Rose-nails, which are drawn four-square in the shank, and commonly in a round tool, as all common twopenny nails are; in some countries all the larger sort of nails are made of this shape. 15. Rother-nails, which have a full head, and are chiefly used in fastening rother-irons to ships. 16. Round-head nails, for fastening on hinges, or for any other use where a neat head is required; these are of several sorts. 17. Scupper-nails, which have a broad head, and are used for fastening leather and canvas to wood. 18. Sharp nails; these have sharp points and flat shanks, and are much used, especially in the West Indies, for nailing soft wood. 19. Sheathing-nails, for fastening sheathing-boards to ships. 20. Square nails, which are used for hard wood, and nailing up wall-fruit. 21. Tacks, the smallest of which serve to fasten paper to wood, the middling for wool-cards, &c. and the larger for upholsterers and pumps.

Nails are said to be toughened when too brittle, by heating them in a fire-shovel, and putting some tallow or grease among them.

Nail, is also a measure of length, containing the sixteenth part of a yard.

NAIS, a genus of the vermes mollusca; the generic character is, body creeping, long, linear, pellucid, depressed; peduncles or feet with small bristles on each side. There are ten species: the digitata is found with single lateral bristles, tail laciniate, in stagnant waters, or the sandy sediment of rivers, with its head attached to the stalk of aquatic plants; it is about 4 lines long.

NAMA, a genus of the digynia order, in the pentandria class of plants: and, in the natural method, ranking under the 13th order, succulentæ. The calyx is pentaphyllous, the corolla quinquepartite, the capsule unilocular and bivalved. There is one species, an annual of Jamaica.

NANDINA, a genus of the class and order hexandria monogynia. The calyx is many-leaved, imbricate; corolla six-petalled. There is one species, a herb of Japan.

NAPÆA, a genus of the polyandria order, in the polyadelphia class of plants; and in the natural method ranking under the 37th order, columniferæ. The calyx is single and cylindric; the arilli coalited and monospermous. There are two species; both of them with perennial roots. Both of them are natives of Virginia and other parts of North America; from the bark of some of the Indian kinds a sort of fine hemp might be procured, capable being woven into very strong cloth. They are easily propagated by seed, which will thrive in any situation.

NAPTHA a name given to the most liquid bitumen; it is light, transparent, and very inflammable. There are several varieties, found chiefly in Italy, and particularly near Modena. Kempfer, however, says, that great quantities are collected in several parts of Persia; naturalists attribute the formation of the liquid bitumens to the decomposition of those that are solid, by the action of the subterraneous fires. Naptha is said to be the lightest, which the fire first disengages: naptha is very volatile, and so combustible, that it catches fire, if any thing burning be brought near it. In Persia, this and the other bitumens are employed for the purpose of giving light in lamps by means of wicks; they may be used also to give heat; for this purpose some naptha is poured on a few handfuls of earth, and kindled with paper, when it burns briskly, but diffuses a thick smoke, which adheres to every thing, and leaves a disagreeable smell. In India, the flame produced by it is worshipped, and the heat it emits is used for dressing victuals; and in some cases it has been successfully employed in paralytic diseases. See Bitumen.

NARCISSUS, a genus of the monogynia order, in the hexandria class of plants; and in the natural method ranking under the 9th order, spathaceæ. There are six petals; the nectarium is funnel-shaped and monophyllous; the stamina are within the nectarium. There are 15 species; the most remarkable are:

1. The bastard narcissus, or common yellow English daffodil, grows wild in great plenty in many of our woods and coppices, and under hedges, in several parts of England. Its commonness renders it of but

little esteem with many; considered, however, as an early and elegant flower, of exceeding hardiness and easy culture, it merits a place in every garden, especially the double.

2. The bicolor, or two-coloured incomparable narcissus; the varieties are, common single-flowered, semi-double-flowered, with the interior petals some white, and some yellow, with sulphur-coloured flowers.

3. The poeticus, poetic daffodil, or common white narcissus, is well known. Of this there are varieties with purple-cupped flowers, yellow-cupped flowers, double-flowered; all of them with entire white petals. It is the antient celebrated narcissus of the Greek and Roman poets, which they so greatly extol for its extreme beauty and fragrance.

4. The bulbocodium. From the large spreading nectarium of this species, which is three or four times longer than the petals, narrow at bottom, and widening gradually to the brim, so as to resemble the shape of some old-fashioned hoop petticoats, it obtained the name hoop-petticoat narcissus.

5. The serotinus, or late-flowering small autumnal narcissus.

6. The tazetta, or multiflorous daffodil, commonly called polyanthus narcissus. The varieties of this are very numerous, consisting of about eight or nine principal sorts; each of which has many intermediate varieties, amounting in the whole to greatly above a hundred in the Dutch florists' catalogues, each variety distinguished by a name according to the fancy of the first raiser of it. They are all very pretty flowers, and make a charming appearance in the flower-borders, &c.; they are also finely adapted for blowing in glasses of water, or in pots, to ornament rooms in winter.

7. The jonquila, or jonquil, sometimes called rush-leaved daffodil. The varieties are, jonquil minor with single flowers; jonquil major with single flowers, starry-flowered, yellow and white flowered, white-flowered, semi-double-flowered, double-flowered, and large double inodorous jonquil; all of them multiflorous, the single in particular; but sometimes the doubles produce only two or three flowers from a spatha, and the singles commonly six or eight. All the sorts have so fine a shape, so soft a colour, and so sweet a scent, that they are among the most agreeable spring-flowers.

8. The calathinus, or multiflorous yellow narcissus.

9. The odorus, odoriferous, or sweet-scented starry-yellow narcissus.

10. The triandrus, or triandrous rush-leaved white narcissus.

11. The trilobus, or trilobate yellow narcissus.

12. The minor, or yellow winter daffodil.

NARCOTICS, in medicine, soporiferous medicines, which excite a stupefaction. See the next article.

NARCOTIC Principle. It has been long known that the milky juices which exude from certain plants, as the poppy, lettuce, &c. and the infusions of others, as of the leaves of the digitalis purpurea, have the property of exciting sleep, or, if taken in doses large enough, of inducing a state resembling apoplexy, and terminating in death. How far these plants owe these properties to certain common principles which they possess, is not known, though it is exceedingly probable that they do. But as a peculiar substance has been detected in opium, the most noted of the narcotic preparations, which possesses narcotic properties in perfection, we are warranted, till further experiments elucidate the subject, to consider it as the narcotic principle, or at least as one species of the substances belonging to this genus.

Opium is obtained from the papaver album, or white poppy, a plant which is cultivated in great abundance in India and the East. The poppies are planted in a fertile soil, and well watered. After the flowering is over, and the seed-capsules have attained nearly their full size, a longitudinal incision is made in them about sun-set for three or four evenings in succession. From these incisions there flows a milky juice, which soon concretes, and is scraped off the plant and wrought into cakes. In this state it is brought to Europe.

Opium thus prepared is a tough brown substance, has a peculiar smell, and a nauseous bitter acrid taste. It becomes softer when held in the warm hand, and burns very readily and strongly. It is a very compound substance, containing sulphat of lime, sulphat of potass, an oil, a resinous body, an extractive matter, gluten, mucilage, &c. besides the peculiar narcotic principle to which probably it owes its virtues as a narcotic.

When water is digested upon opium, a considerable portion of it is dissolved, the water taking up several of its constituents. When this solution is evaporated to the consistence of a syrup, a gritty precipitate begins to appear, which is considerably increased by diluting the liquid with water. It consists chiefly of three ingredients; namely, resin, oxygenized attractive, and the peculiar narcotic principle which is crystallized. When alcohol is digested on this precipitate, the resin and narcotic substances are taken up, while the oxygenised extractive remains behind. The narcotic principle falls down in crystals as the solution cools, still however coloured with resin. But it may be obtained tolerably pure by repeated solutions and crystallizations.

Water is incapable of dissolving the whole of opium. What remains behind still contains a considerable portion of narcotic principle. When alcohol is digested on this residuum, it acquires a deep red colour; and deposits, on cooling, crystals of narcotic principle, coloured by resin, which may be purified by repeated crystallizations. The narcotic principle obtained by either of these methods possesses the following properties:

Its colour is white. It crystallizes in rectangular prisms with rhomboidal bases. It has neither taste nor smell.

It is insoluble in cold water, soluble in about 400 parts of boiling water, but precipitates again as the solution cools. The solution in boiling water does not affect vegetable blues.

It is soluble in 24 parts of boiling alcohol and 100 parts of cold alcohol. When water is mixed with the solution, the narcotic principle precipitates in the state of a white powder.

Hot ether dissolves it, but lets it fall on cooling.

When heated in a spoon it melts like wax. When distilled it froths, and emits white vapours, which condense into a yellow oil. Some water and carbonat of ammonia pass into the receiver; and at last carbonic acid gas, ammonia, and carbureted hydrogen gas, are disengaged. There remains a bulky coal, which yields traces of potass. The oil obtained by this process is viscid, and has a peculiar aromatic smell and an acrid taste.

It is very soluble in all acids. Alkalies throw it down from these solutions in the state of a white powder.

Alkalies render it rather more soluble in water. When they are saturated with acids, the narcotic principle falls down in the state of a white powder, which is redissolved by adding an excess of acid.

Volatile oils, while hot, dissolve it; but, on cooling, they let it fall in an oleaginous state at first, but it gradually crystallizes.

When treated with nitric acid, it becomes red and dissolves; much oxalic acid is formed, and a bitter substance remains behind.

When potass is added to the aqueous solution of opium, the narcotic principle is thrown down; but it retains a portion of the potass.

Its solubility in water and alcohol, when immediately extracted from opium, seems to be owing to the presence of resin and extractive matter, both of which render it soluble.

It possesses the properties of opium in perfection. Derosne tried it upon several dogs, and found it more powerful than opium. Its bad effects were counteracted by causing the animals to swallow vinegar. This substance is known to be of equal service in counteracting the effects of opium. Derosne supposes that the efficacy of vinegar may be owing to the readiness with which it dissolves the narcotic principle.

Many other substances beside opium possess narcotic virtues; but hitherto they have not been examined by chemists with much attention. The most remarkable are the following:

1. The lactuca virosa, and the sativa or garden-lettuce, and indeed all the lactucas, yield a milky juice, which, when inspissated, has very much the appearance of opium, and possesses the same properties. Indeed, Dr. Coxe of Philadelphia affirms, that as good opium may be obtained from the garden-lettuce as from the poppy. The milky juice is obtained by incisions at the time when the lettuce is running to seed. The resemblance between the inspissated juice of the lactuca virosa and opium is striking.

2. The leaves of the atropa belladonna, or deadly nightshade, and indeed the whole plant, are remarkably narcotic; and when taken in too great doses produce blindness, convulsions, coma, and death.

3. The leaves of the digitalis purpurea, or fox-glove, are still more powerful if possible. They lower the pulse in a remarkable degree, and, like several other very poisonous narcotics, promote the discharge of urine.

4. Hyoscyamus, niger or henbane.

5. Conium maculatum, or hemlock.

6. Datura stramonium.

7. Ledum palustre.

To these may perhaps be added the prunus laurocerasus, and the leaves of nicotiana tabacum or tobacco. The list, indeed, might be easily increased; almost all the plants belonging to the natural order of luridæ possessing narcotic properties; but as we are completely ignorant of the chemical properties of these plants, it is unnecessary to be more particular.

Narcotic salt. See Boracic acid.

NARDUS, a genus of the monogynia order, in the triandria class of plants; and in the natural method ranking under the 4th order, gramina. There is no calyx; the corolla is bivalved. There are three species. This plant was highly valued by the antients both as an article of luxury and medicine. The unguentum nardinum was used at baths and feasts as a favourite perfume. Its value is evident from that passage of scripture, where our Saviour's head was anointed with a box of it, with which Judas found fault. From a passage in Horace it appears that this ointment was so valuable among the Romans, that as much as could be contained in a small box of precious stone was considered as a sort of equivalent for a large vessel of wine, and a proper quota for a guest to contribute at an entertainment. The plant had a great character among the antients as a medicine, both internally taken and externally applied. Its sensible qualities, indeed, promise it to be of considerable efficacy in some cases, as it has a pungency of taste superior to contrayerva, and little inferior to serpentaria.

NATIONAL DEBT, the sum which is owing by a government to individuals who have advanced money for public purposes, either in anticipation of the produce of particular branches of the revenue, or on credit of the general power which the government possesses of levying the sums necessary to pay interest for the money borrowed, or to repay the principal. The practice of borrowing money on account of the state has been found so convenient, that almost every nation of modern Europe is encumbered with a considerable debt: the different manner of conducting hostilities in antient and modern times has perhaps rendered this practice absolutely necessary, as the vast expences with which wars are now attended could not possibly be defrayed during the time of their continuance, without producing the greatest distress, or perhaps absolute ruin, to the countries engaged in them. In antient times wars were not only shorter in their duration, but were conducted on principles which rendered great pecuniary supplies less necessary than at present; the whole contest was a scene of plunder and devastation, the persons and property of the enemy were at the entire disposal of the conqueror, and the greater part of the plunder was accounted for to the public. The arms made use of were much less expensive than those of modern warfare, and the extent of naval operations, the great source of national expenditure in modern times, was comparatively trifling. Sir J. Sinclair has justly observed, that had the rage of equipping numerous fleets, and building ships of great magnitude and dimensions, never existed, hardly any state in Europe would have been at this time in debt.

The principal advantages arising from national debts, and the system of credit on which they are founded, are, 1. The resource they afford in great emergencies, which gives a greater permanency to states, which in former times, for want of such occasional resources, were more liable to internal derangements and to foreign subjugation. 2. The equalization of taxes. If the supplies were raised within the year, and the expences of war were considerable, every individual would be obliged, in consequence of the additional weight of his contributions, greatly to curtail his expences; and the employment of the poor, and the consumption of the rich, would be considerably diminished; whereas, when taxes are nearly equal, in time of peace and war, the value of every species of property, of industry, and the circulation of wealth, are maintained on as regular, steady, and uniform a footing, as the uncertainty and instability of human affairs will admit. 3. They retain money in the country, which would otherwise be sent out of it; public debts have more influence in this respect than all the laws against the exportation of specie that ever were made. 4. They promote circulation. The taxes which they occasion on the property of the rich, and the encouragement they hold out to the avaricious, prevent the accumulation of private hoards, and bring the whole money and personal property of a country into employment. 5. They attach the people to the government; for every individual creditor is led by his own interest to support the authority on the prosperity and existence of which the security of his property depends. The extent of this influence is so well understood, that it is not probable the government of any country where a public debt has once existed, will ever permit it to be wholly paid off. 6. They encourage industry and the acquirement of property, by the facility with which individuals can lay out the surplus of their profits, without the risk of commercial bankruptcies, or the unavoidable expences and small advantage which landed estates yield, and receive interest on their capital with certainty and regularity.

The disadvantages attending the system of incurring national debts, are, 1. The facility of carrying on war being much increased: while large sums can be easily borrowed, it may frequently cause wars to be protracted, which would have been much sooner brought to a termination, had the governments engaged in them experienced the difficulty of defraying the whole expence by taxation. 2. The value of the property of those who have lent their money to the state, depending on the public tranquillity, inclines them to support indiscriminately the measures of the government, whatever may be their tendency: they are interested both to preach and practice apathy under every invasion of the constitution of their country. 3. The increase of taxes to pay the interest of the debt, produces an increase in the price of all the necessaries of life, and renders it difficult for the manufacturers of a state in which this system has been carried to a great height, to maintain a successful competition with the subjects of other powers, who may be in a less embarrassed situation. 4. When a nation is encumbered with debts, a pernicious spirit of gambling is encouraged: stock-jobbing, with all its train of evil consequences, necessarily arises; and a moneyed interest is erected, the sole employment of which is that of drawing every possible advantage from the wants of individuals, or the necessities of the public. 5. Public debts have a very material influence on the distribution of property. Every new loan must be procured from persons already possessing considerable wealth, and such persons will not lend their money without the expectation of making a profit by it; the increase of the debt is, therefore, to them a source of increasing wealth, to which their share of the additional taxes attendant upon it bears but a small proportion; and if the government possesses no revenue but what is drawn from the people, whatever it pays to one description of men must be drawn principally from others: thus the additional income acquired by moneyed men, by taking advantage of the necessities of the state, is, in fact, a portion of the income of their less affluent fellow-citizens, which is transferred to them through the medium of the government, and which, in a much greater proportion than it increases their wealth, must render those poorer from whom it is drawn.

The practice of incurring national debts on extraordinary occasions had been resorted to in other countries long before it was adopted in England. The Italian republics seem to have begun it; Genoa and Venice had both considerable debts. Spain was deeply in debt before the end of the 16th century, about a hundred years before England owed a shilling. In France the funding system was introduced about the year 1678; and previously to the revolution, the debt of that country was 142 millions sterling; two-fifths of which consisted of life-annuities, which in this estimate are taken at eleven years purchase.

The national debt of Great Britain commenced in the reign of William III. The war which began in 1689 being very expensive, and the grants of parliament not supplying money so fast as it was wanted, the expedient of mortgaging part of the public revenue was adopted. At first the produce of particular taxes was assigned for repayment of the principal and interest of the money borrowed; large sums were also raised on life-annuities, and annuities for terms of years; and the funds established for payment of these debts being generally inadequate to the charge upon them, occasioned great deficiencies, which, at the conclusion of the war, amounted to 5,160,459*l.* 14*s.* $9\frac{1}{4}$*d.* and were charged on the continuation of various duties which had been granted for short terms. The total amount of the funded and unfunded debts in the year 1697, was 19,950,945*l.* 19*s.* $8\frac{3}{4}$*d.* The frequent anticipation of the different funds, and their general deficiency from the diminution of the revenue, in consequence of which the interest due upon money lent to government was often long in arrear, reduced public credit at this period to a very low ebb, and rendered persons who had money very reluctant in advancing it to the government, though paid what would now be called an exorbitant interest: the accumulation of the public debts caused serious apprehensions among people of property of all descriptions.

The great expence of the war during the reign of queen Anne was chiefly defrayed by the sale of annuities for different terms, but mostly for 99 years; and money was not only borrowed to pay the interest of loans, but often to pay the interest of that interest; or, what is much the same thing, the arrears of interest were converted into principal, by which means, and from great mismanagement of the public finances, the debt rapidly increased, and on the 31st December 1716, amounted to 48,364,501*l.* 8*s.* 4*d.* This amount was considered, in the language of the king and parliament, as an "insupportable weight;" and the house of commons expressed their determination to apply themselves, with all possible diligence and attention, to the great and necessary work of reducing by degrees this heavy burthen, as the most effectual means of preserving to the public funds a real and certain security.

The current rate of interest having lowered considerably, a plan was adopted for reducing the rate of interest payable on such part of the public debts as carried 6 per cent. interest, which causing a surplus in the funds appropriated to the payment of the interest, the overplus remaining, after satisfying the charges upon the respective funds, was formed into a separate fund, under the title of the sinking fund, for the express purpose of discharging such national debts as were incurred before December 1716, and "for no other use, intent, or purpose, whatsoever." This arrangement was well calculated for effecting a gradual reduction of the amount of the debt, and gave a new confidence to the public creditors, from a persuasion that the provisions made would prevent the inconveniences which had formerly arisen from the interest of particular debts being frequently long in arrear; and that instead of the depression of the current value of their securities, which generally attends the increase of public debts, this value would increase in proportion to the progress of redemption. The public had also a distant hope at least of being relieved from some of the many taxes which it had been necessary to impose for paying the interest of the debt, the pernicious effects of which, both on the foreign trade and the internal state of the country, began to be sensibly felt.

The expectations entertained from the sinking fund were, however, soon disappointed; as the period of its strict application to the purpose for which it was established did not exceed 10 or 11 years. The famous South Sea scheme was likewise to have furnished a considerable sum to be employed in the reduction of the public debts; instead of which it increased their amount by an addition to the capital of 3,034,769*l.* 11*s.* 11*d.*, while the annual charge was rather augmented than diminished by the allowance for management on the increased capital: a further reduction of a part of the interest was however secured by this transaction.

In 1727 the interest payable on 29,962,979*l.* 12*s.* 9¼*d.* South Sea stock and annuities, and on 7,775,027*l.* 17*s.* 10½*d.* due to the Bank, was reduced from 5 to 4 per cent. which produced such an important augmentation of the sinking fund, that had it been faithfully applied to the purpose for which it was intended, and received no other increase than what would have arisen from a judicious application of it, the national debt would at this time have been wholly annihilated. During the reign of George I. the fund continued to be appropriated to the purposes for which it was formed: little progress, however, was made in discharging the public debts; for at the same instant that old incumbrances were thus paid off, new debts were contracted; so that at the end of the year 1727, the total of the funded debt amounted to 51,258,939*l.* 4*s.* 2¾*d.*, of which it must be remembered that upwards of three millions arose from the additional capital created by the South Sea company's subscription.

The whole sum paid off by the sinking fund from its establishment to the year 1739, was only 8,328,354*l.* 17*s.* 11*d.*; and the total amount of the debt at this period 46,954,623*l.* 3*s.* 4*d.*½.

The war with Spain and France, which began in this year, increased the debt to 78,293,313*l.* 1*s.* 10*d*¾., the interest on which amounted to 3,061,004*l.* 11*s.* 1¼*d.* per ann.

The interest of money, which had risen during the war to upwards of 4 per cent. fell, when the cessation of hostilities terminated the loans of government, to 3 per cent.; and the administration seized the moment of increased prosperity to propose another important reduction of interest. Towards the end of 1749, 3 per cent. stock had been for some months above par: an act was therefore passed by which the interest was reduced on all the public debts redeemable by law, which then carried 4 per cent. interest, forming together a capital of 57,703,475*l.* 6*s.* 4½*d.* The proprietors, on signifying their consent to the reduction, were to have 4 per cent. interest to the 25th December following, thence 3½ per cent. till 25 December, 1757, and afterwards 3 per cent. per annum. Upwards of three millions remained unsubscribed, which was therefore paid off, by money borrowed at 3 per cent., and thus a saving of 612,735*l.* per annum was effected, which ought to have contributed materially to the reduction of the debt. Little progress, however, was made in diminishing the capital of the debt; and at the commencement of the war in 1755 it amounted to 74,980,886*l.* 8*s.* 2¼*d.*

The great expences of the war rendered the loans of greater magnitude than had ever before been raised, and the debts incurred were somewhat increased by the practice of entitling the persons lending the money to a greater capital than the sum actually advanced; so that at the end of the war, including the loan of 1763, they amounted to 141,691,313*l.* 13*s.* 4*d.*, and the annual interest to 4,706,734*l.* 11*d.*

During the succeeding 12 years of peace, little was done in reality towards diminishing the amount of the debt; for although in each year from 1765 to 1775, some small portion of the funded debt was paid off, the whole amounted to only 11,983,553*l.* being a less amount than had sometimes been borrowed in one year of war; and the debt was far from being diminished even this amount, as during the same period a new debt of 5,052,500*l.* was contracted, by borrowing money on 3 per cent. stock, in order to redeem 4 per cents.

The American war was entered into with a funded debt of 132,343,051*l.*, including an estimated value of the long annuities and exchequer annuities, and an unfunded debt of about 3,600,000*l.*, making together 135,943,051*l.* the interest on which amounted to 4,476,821*l.* per annum. The expences of this war greatly exceeded those which had preceded it; and the increase of the debt was much greater than had ever been incurred by any country in the same space of time. The following statements will shew the extent of the sums borrowed, and the additions thus made to the annual burthens of the country:

	Money bor.	Debt created.	Interest.
1776	2,000,000	2,150,000	64,500
1777	5,000,000	5,000,000	225,000
1778	6,000,000	6,000,000	330,000
1779	7,000,000	7,000,000	472,500
1780	12,000,000	12,000,000	697,500
1781	12,000,000	21,000,000	660,000
1782	13,500,000	20,250,000	793,125
1783	12,000,000	15,000,000	560,000
1784	6,000,000	9 000,000	316,500
	£75,500,000	97,400,000	4,119,125

From which it appears that a nominal capital of 21,900,000*l.* was added to the sum of 75,500,000*l.* actually borrowed, and that the interest on the whole amounted to 5*l.* 9*s.* 1*d.* per cent., on which the perpetual interest was equal to 4*l.* 6*s.* per cent. on the whole sum. In addition to the above sums, a very considerable amount of navy debt was funded after the conclusion of the war, which being properly part of the expences of it, the total debt incurred by the American war may be stated as follows:

	Debt created.	Interest.
In 3 per cents.	64,648,000	1,939,440
4 per cents.	32,750,000	1,310,000
5 per cents.	17,869,992	893,499
Terminable annuities		869,623
	£115,267,992	5,012,562

The whole amount of the funded and unfunded debts, including a valuation of the terminable annuities, was on the 5th Jan. 1786, 268,100,379*l.* 18*s.* 8*d.*, and the amount of the annual interest 9,512,232*l.* 7*s.* 9*d.*

The magnitude of the public debt, and the consequent low price of the funds, appear at this period to have engaged the serious attention of the government; in consequence of which some new taxes were imposed, in order to raise a surplus of revenue, as the foundation of a plan for establishing a new sinking fund. In order to ascertain what portion of the revenue might be appropriated to this purpose, a select committee of the house of commons was appointed to examine and state the accounts presented to the house relating to the public income and expenditure, and to report what might be expected to be the annual amount of the income and expenditure in future. On the 21st March, 1786, the committee made their report; and conceiving that the circumstances of the times rendered any average drawn from the amount of the revenue in former periods in a great degree inapplicable to the situation of the country, they formed an account of the public receipt and expenditure to Michaelmas 1785, and to January 1786, from which it appeared, that at the former period there was a surplus of 901,001*l.*, and at the latter a surplus of 919,299*l.* As it was evident that a fund of less than one million per annum would be very inadequate to the purpose for which it was designed, new taxes were imposed for raising the surplus revenue to this sum; and, in order the more effectually to prevent ministers from diverting it to any other purpose, the mode was adopted which had been frequently suggested, of vesting the annual sums in the hands of commissioners: some other judicious regulations were also established by the act passed for this purpose. See Sinking Fund.

In the year 1789, it was found necessary to borrow 1,002,140*l.* on a tontine scheme, and 187,000*l.* to replace the like sum which had been issued out of the civil list revenue, as a loan to the prince of Orange: the latter was raised on annuities for 18¾ years. The total amount of the public debt in the year 1792, being the year previous to the war with the French republic, was, according to the official account, 238,231,248*l.*; but including the value of the terminable annuities, and the amount of the unfunded debt, the total was 268,267,272*l.* 1*s.* 7*d.*, the annual interest and charges of management on which amounted to 9,752,673*l.* 14*s.* 8*d.* From this amount, however, a deduction is to be made of the stock which had been redeemed by the operation of the sinking fund. With this formidable burthen on the property and industry of the country, a war was entered into, which from the enormous expenditure attending it, increased the amount of the national debt in a degree beyond all former precedent or conjecture. The loan of the year 1793 was raised wholly on 3 per cent. stock, and those of the subsequent years being also raised chiefly on this description of stock, an unnecessary addition has been made to the capital of the debt, and the charge for management has been considerably augmented, as the allowance to the bank on this account is computed on the capital created. In the third year of the war the amount of the loan was considerably greater than had ever before been borrowed in one year; but still larger sums were raised in some of the succeeding years. The natural consequence of such a rapid accumulation of debt was a great depreciation of the current prices of the public funds, so that the government was obliged to allow a very high interest for the money borrowed; and towards the end of the year 1797, many persons seemed to entertain an apprehension that the funding system had been extended nearly to its limits; in consequence of this opinion, various expedients were successively tried for raising a considerable part of the war expenditure within the year; none of these projects fully succeeded, but they certainly rendered the sums which it was necessary to borrow, somewhat less in amount than they must otherwise have been; still, however, they were of unprecedented magnitude: and in 1802, after the conclusion of the war, it was still found necessary to borrow twenty-five millions more, to make good expences of the war remaining unprovided for. The total amount of the national debt at Midsummer 1802, including the stock created by the imperial loans, and estimating the unfunded debt at 15,500,000*l.* was 619,303,027*l.* 9*s.* 6*d.*, the annual charge of which for interest and management amounted to 21,557,728*l.* 15*s.* 6*d.* From this amount is to be deducted the stock bought up by the commissioners, and transferred to them for redemption of land-tax.

PROGRESS OF THE NATIONAL DEBT, FROM ITS COMMENCEMENT TO MIDSUMMER 1802.

	Capital.	Interest.
National Debt at the Revolution, 1688	£. 664,263	39,855
Increase during the reign of William IIId.	15,730,439	1,271,087
Amount at the accession of Queen Anne	16,394,702	1,310,942
Increase during the reign of Queen Anne	31,969,799	1,841,582
Amount at establishment of Sinking Fund, 1716	48,364,501	3,152,524
Increase during the reign of Geo. I.	4,654,654	
Decrease of annual charge	- - -	941,958
Amount at the accession of Geo. IId.	53,019,155	2,210,566
Decrease during the Peace	6,064,532	246,541
Amount at commencement of the War, 1739	46,954,623	1,964,025
Increase during the War	31,338,689	1,096,979
Amount at the end of the War in 1748	78,293,312	3,061,004
Decrease during the Peace	3,312,426	389,364
Amount at the commencement of the War, 1755	74,980,886	2,671,640
Increase during the War	66,710,427	2,035,094
Amount at the end of the War, 1762	141,691,313	4,706,734
Decrease during the Peace	5,748,262	229,913
Amount at commencement of the American War	135,943,051	4,476,821
Increase during the War	132,157,328	5,035,411
Amount at the conclusion of the American War	268,100,379	9,512,232
Increase in the year 1789	1,189,140	56,863
Amount in 1789	269,289,519	9,569,095
Redeemed during the Peace	9,441,850	283,255
Amount at the commencement of the War, 1793	259,847,669	9,285,840
Increase during the War	350,013,508	11,988,633
	609,861,177	21,274,473
Redeemed during the War	69,243,336	2,089,220
Amount at conclusion of the War in 1802	540,617,841	19,185,253

Since the period at which the above statement terminates, another war has been entered into, which has already added many millions to the public debt; but as the sum to which it may be increased is beyond the reach even of probable estimate, we can only give the following statement of the total amount of the Debt on the 5th January, 1806, which will also shew the different descriptions of Stock and Annuities of which it consists:

NATIONAL DEBT OF GREAT BRITAIN.

	Capital.			Interest and Management.		
5 per Cent. Consolidated Annuities	£. 41,389,136	8	4	£. 2,088,081	18	7
5 per Cent. Annuities, 1797 and 1802	9,088,902	16	3	458,535	2	10
4 per Cent. Consolidated Annuities	49,725,084	17	2	2,011,379	13	7
3 per Cent. Reduced Annuities	137,246,269	3	7	4,179,148	17	2
3 per Cent. Consolidated Annuities	376,707,982	2	0¼	11,470,758	0	3
3 per Cent. Deferred Annuities	1,740,625	0	0	——		
3 per Cent. Annuities, 1726	1,000,000	0	0	30,450	0	0
Bank Stock	11,686,800	0	0	356,502	3	5
South Sea Stock	3,662,784	8	6	}		
Old South Sea Annuities	11,907,470	2	7	} 735,974	13	11

South Sea Annuities, 1751	1,919,600	0	0	58,325	15	6
Imperial 3 per Cent. Annuities	7,502,633	6	8	228,455	3	8
Value of the Long Annuities	19,969,799	12	6	1,075,669	4	11
Do. of the Short Annuities	786,599	5	1	423,039	5	9
Do. of Imperial Annuities	2,184,694	7	9	232,587	10	0
Do. of the Life Annuities	403,779	9	6	67,296	11	7
Annuities on Lives, with Survivorship, 1765	18,000	0	0	540	0	0
Tontine Annuities, 1789	280,452	18	0	20,032	7	0
Value of Exchequer Annuities	23,668	0	0	23,668	0	0
	685,739,112	0	9¼	23,460,444	8	2
Redeemed by Sinking Fund	104,701,999	0	0	3,170,073	19	4
	581,037,113	0	9¼	20,290,370	8	10
Transferred for Land Tax redeemed	22,000,000	0	0	660,000	0	0
Total Funded Debt	559,037,113	0	9¼	19,630,370	8	10
Navy, Victualling, and Transport Debt	5,500,000	0	0	}		
Army, Barracks, Ordnance, &c.	3,000,000	0	0	} 681,000	0	0
Treasury Bills, &c.	1,200,000	0	0	}		
Exchequer Bills	13,000,000	0	0	}		
Total of the Nat. Debt and the ann. interest thereon,	581,737,113	0	9¼	20,311,370	8	10

For the comparative value of the different funds, and the mode of transacting business therein, see Public Funds.

NATRUM. See Soda.

NATIVITY, in old law-books, signifies villainage or servitude.

NATURAL HISTORY. The object of this branch of science may be divided into two heads; the first teaches us the characteristics, or distinctive marks, of each individual object, whether animal, vegetable, or mineral; the second makes us acquainted with all its peculiarities, as to its habits, its qualities, and its uses. To assist in attaining the first, it is necessary to adopt some system of classification, in which individuals that agree in particular points may be arranged together. In this work we have adopted the Linnæan system, as the most simple and perfect that has been presented to the public.

A knowledge of the second head is only gained by a patient investigation of each particular object; for this we refer the reader to the several genera described in these volumes, under which we have endeavoured to give a brief account of all the interesting and material facts.

The study of natural history consists in the collection, arrangement, and exhibition, of the various productions of the earth. These are divided into the three grand kingdoms of nature, the boundaries of which meet together in the zoophytes. See Zoophytes.

Minerals inhabit the interior parts of the earth, in rude and shapeless masses. They are bodies concrete without life and sensation. See Mineralogy.

Vegetables clothe the surface with verdure, imbibe nourishment through bibulous roots, breathe by leaves, and continue their kind by the dispersion of seed within prescribed limits. They are organized bodies, and have life and not sensation. See Botany.

Animals adorn the exterior parts of the earth, respire and generate eggs; are impelled to action by hunger, affections, and pain; and by preying on other animals and vegetables, restrain within proper bounds and proportions the numbers of both. They have organized bodies, and have life, sensation, and the power of locomotion.

Man, the governor and subjugator of all other beings, is, by his wisdom alone, able to form just conclusions from such things as present themselves to his senses, which consist of natural bodies. Hence the first step of wisdom is to know these bodies; and to be able, by marks imprinted on them by the God of nature, to distinguish them from each other, and to affix to every object its proper name. These are the elements of this science; this is the great alphabet of nature: for if the name is lost, the knowledge of the object is lost also.

The method adopted in natural history, indicates that every body may, by inspection, be known by its peculiar name, and this points out whatever the industry of man has been able to discover concerning it; so that, amidst the greatest apparent confusion, the greatest order is visible.

The Linnæan system is divided into five branches, each subordinate to the other: these are, class, order, genus, species, and variety, with their names and characters. In this arrangement, the classes and orders are arbitrary, the genera and species are natural.

Of the three grand divisions above referred to, the animal kingdom ranks highest in comparative estimation, the next the vegetable, and last is the mineral kingdom.

To the vegetable and mineral kingdoms, we have already referred under the distinct heads Botany and Mineralogy: with regard to the animal kingdom, we observe that,

Animals enjoy sensation by means of a living organization, animated by a medullary substance; perception by nerves; and motion by the exertion of the will. They have members for the different purposes of life; organs for their different senses; and faculties or powers for the application of their different perceptions. They all originate from an egg. Their external and internal structure, habits, instincts, and various relations to each other, will be found under the different genera. See also Comparative Anatomy.

The division of animals is into six classes, formed from their internal structure.

1. Mammalia	Heart with 2 auricles & 2 ventricles: blood warm and red.	viviparous
2 Birds		oviparous
3. Amphibia	Heart with 1 auricle & 1 ventricle: blood cold and red.	lungs voluntary
4. Fishes		
5. Insects	Heart with 1 auricle, ventricle 0; sanies cold and white.	have antennæ
6. Vermes		tentacula.

The following is an abstract of Linnæus's Systema Naturæ, by Gmelin.

Class I. Mammalia.

Order.	Genera.	Species.
Primates	4	88
Bruta	7	25
Feræ	10	186
Glires	10	129
Pecora	8	90
Belluæ	4	25
Cete	4	14
7	47	557

Class II. Aves.

Order.	Genera.	Species.
Accipitres	4	271
Picæ	26	663
Anseres	13	314
Grallæ	20	326
Gallinæ	10	129
Passeres	17	983

Mollusca	31	538
Testacea	36	2525
Zoophita	15	498
Infusoria	15	191
5	118	4036.

Natural philosophy, that which considers the powers and properties of natural bodies, and their actions on one another.

Our knowlege of nature being now found to result entirely from well-conducted experiments, the term natural philosophy has been latterly compounded with that of experimental philosophy, and indeed they seem nearly to mean the same thing. See Experimental Philosophy. Natural philosophy is, however, obviously rather a system or aggregate of several branches of knowledge, than a simple and uniform science. These branches, therefore, it was necessary to treat of under separate articles, to which we must content ourselves with referring upon this occasion, arranging them in the order in which we think they may be studied with most advantage, viz. Attraction, Gravitation, and Gravity, Magnetism, Motion, Mechanics, Pneumatics, Hydrostatics, Hydraulics, Electricity, Galvanism, Optics, Astonomy; to which we may add Chemistry and Mineralogy.

NATURALIZATION, is when an alien-born is made the king's natural subject.

Hereby an alien is put in the same state as if he had been born in the king's liegeance, except only that he is incapable of being a member of the privy council or parliament, and of holding any office or grant. No bill for a naturalization can be received in either house of parliament, without such disabling clause in it; nor without a clause disabling the person from obtaining any immunity in trade thereby, in any foreign country, unless he shall have resided in Britain seven years after the commencement of the session in which he is naturalized. Neither can any person be naturalized, or restored in blood, unless he has received the sacrament within one month before bringing in of the bill, and unless he also takes the oaths of allegiance and supremacy in the presence of the parliament. 1 Black. 374. See Alien.

NAVAL stores comprehend all those particulars made use of, not only in the royal navy, but in every other kind of navigation; as timber for shipping, pitch, tar, hemp, cordage, sail-cloth, gunpowder, ordnance and fire-arms of every sort, ship-chandlery wares, &c.

NAUCLÆA, a genus of the pentandria monogynia class and order. The corolla is funnel-form; seed one, inferior, two-celled; receptacle, common globular. There are four species, trees of the East Indies, &c.

NAVIGATION, the art of conducting a ship from one port to another. The main end of all practical navigation is, to conduct the ship in safety to her destined port; and for this purpose it is of the utmost consequence to know in what particular part of the surface of the globe she is at any particular time. This can only be done by having an accurate map of the sea-coasts of all the countries of the world, and, by tracing out the ship's progress along the map, to know at what time she approaches the desired haven, or how she is to direct her course in order to reach it. It is therefore a matter of great importance for navigators to be furnished with maps, or charts, as they are called, not only very accurate in themselves, but such as are capable of having the ship's course easily traced upon them, without the trouble of laborious calculations, which are apt to create mistakes. The navigator should have a perfect knowledge of the figure and motion of the earth; the various real and imaginary lines upon it, so as to be able to ascertain the distance and situation of places with respect to one another. He should also be acquainted with the several instruments employed in measuring the ship's way; such as the log, half-minute glass; quadrant to take the altitude of the sun and stars; compass to represent the sensible horizon; and azimuth compass to take the azimuth and amplitude of the sun, in order to know the variation of the magnetic needle. He should have an accurate knowledge of maps and charts of the lands and seas, together with the depth of water, the times and setting in of the tides upon the coasts that he may have occasion to visit; also the currents; of the mould and trim of the ship, and the sail she bears, that so a due allowance may be made for lee-way. By the help of these, he may at all times know the place the ship is in, which way he must steer, and how far he has to run to gain his intended port.

The names of the two great divisions of navigation are taken merely from the kind of charts made use of. Plane sailing is that in which the plane chart is made use of; and Mercator's sailing, or globular sailing, is that in which Mercator's chart is used. In both these methods, it is easy to find the ship's place with as great exactness as the chart will allow, either by the solution of a case in plane trigonometry, or by geometrical construction.

Of Plane sailing. As a necessary preliminary to our understanding this method of navigation, we shall here give the construction of the plane chart.

1. This chart supposes the earth to be a plane, and the meridians parallel to one another; and likewise the parallels of latitude at equal distances from one another, as they really are upon the globe. Though this method is in itself evidently false; yet, in a short run, and especially near the equator, an account of the ship's way may be kept by it tolerably well.

Having determined the limits of the chart, that is, how many degrees of latitude and longitude, or meridional distance (they being in this chart the same), it is to contain: suppose from the lat. of 20° N. to the lat. of 71° N., and from the longitude of London in 0 deg. to the long. of 50° W.; then choose a scale of equal parts, by which the chart may be contained within the size of a sheet of paper on which it is intended to be drawn.

Make a parallelogram ABCD (Plate Navigation. fig. 1), the length of which AB from north to south shall contain 51 degrees, the difference of latitude between the limits of 20° and 71°; and the breadth AD from east to west shall contain the proposed 50 degrees of longitude, the degrees being taken from the said scale, and this parallelogram will be the boundaries of the chart.

About the boundaries of the chart make scales containing the degrees, halves, and quarters of degrees (if the scale is large enough); drawing lines across the chart through every 5 or 10 degrees; let the degrees of latitude and longitude have their respective numbers annexed, and the sheet is then fitted to receive the places intended to be delineated thereon.

On a straight slip of pasteboard, or stiff paper, let the scale of the degrees and parts of degrees of longitude, in the line AD, be laid close to the edge; and the divisions numbered from the right hand towards the left, being all west longitude.

Seek in a geographical table for the latitudes and longitudes of the places contained within the proposed limits; and let them be written out in the order in which they increase in latitude.

Then, to lay down any place, lay the edge of the pasteboard scale to the divisions on each side the chart, shewing the latitude of the place; so that the beginning of its divisions falls on the right-hand border AB; and against the division shewing the longitude of the given place make a point, and this gives the position of the place proposed; and in like manner are all the other places to be laid down.

Draw waving lines from one point to the other, where the coast is contiguous, and thus the representation of the lands within the proposed limits will be delineated.

Write the names to the respective parts, and in some convenient place insert a compass, and the chart will be completed.

2. The angle formed by the meridian and rhumb that a ship sails upon, is called, as we have said, the ship's course. Thus, if a ship sails on the N.N.E. rhumb, then her course will be 22° 30′; and so of others, as is manifest from the following table of the angles which every point of the compass makes with the meridian.

North.	South.	Points.	D. M.	North.	South.
		$\frac{1}{4}$	2.49		
		$\frac{1}{2}$	5.37		
		$\frac{3}{4}$	8.26		
N. by E.	S. by E.	1	11.15	N. by W.	S. by W.
		1 $\frac{1}{4}$	14. 4		
		1 $\frac{1}{2}$	16 52		
		1 $\frac{3}{4}$	19.41		
N. N. E.	S. S. E.	2	22.30	N. N. W.	S. S. W.
		2 $\frac{1}{4}$	25.19		
		2 $\frac{1}{2}$	28. 7		
		2 $\frac{3}{4}$	30.56		
N E. by N.	S. E. by S.	3	33.45	N. W. by N.	S. W. by S.
		3 $\frac{1}{4}$	36.34		
		3 $\frac{1}{2}$	39.22		
		3 $\frac{3}{4}$	42.11

		7 $\frac{3}{4}$	87.11		
	East.	8	90. 0	West.	

3. The distance between two places lying on the same parallel counted in miles of the equator, or the distance of one place from the meridian of another counted as above on the parallel passing over that place, is called meridional distance; which, in plane sailing, goes under the name of departure.

4. Let A (fig. 2), denote a certain point on the earth's surface, AC its meridian, and AD the parallel of latitude passing through it; and suppose a ship to sail from A on the N. N.E. rhumb till she arrives at B; and through B draw the meridian BD, (which, according to the principles of plane sailing, must be parallel to CA,) and the parallel of latitude BC; then the length of AB, viz. how far the ship has sailed upon the N. N.E. rhumb, is called her distance; AC or BD will be her difference of latitude, or northing: CB will be her departure, or easting; and the angle CAB will be the course. Hence it is plain, that the distance sailed will always be greater than either the difference of latitude or departure; it being the hypothenuse of a right-angled triangle, whereof the other two are the legs; except the ship sails either on a meridian or a parallel of latitude: for if the ship sails on a meridian, then it is plain, that her distance will be just equal to her difference of latitude, and she will have no departure; but if she sails on a parallel, then her distance will be the same with her departure, and she will have no difference of latitude. It is evident also from the figure, that if the course is less than 4 points, or 45 degrees, its complement, viz. the other oblique angle, will be greater than 45 degrees, and so the difference of latitude will be greater than the departure; but if the course is greater than 4 points, then the difference of latitude

will be less than the departure; and lastly, if the course is just 4 points, the difference of latitude will be equal to the departure.

5. Since the distance, difference of latitude, and departure, form a right-angled triangle, in which the oblique angle opposite to the departure is the course, and the other its complement; therefore, having any two of these given, we can (by plane trigonometry) find the rest; and hence arise the cases of plane-sailing, which are as follow:

Case I. Course and distance given, to find the difference of latitude and departure.

Example. Suppose a ship sails from the latitude of 30° 25′ north, N. NE. 32 miles (fig. 3). Required the difference of latitude and departure, and the latitude come to. Then (by right-angled trigonometry) we have the following analogy for finding the departure, viz.

As radius - - - - - -		10.00000
to the distance AC -	32.	1.50515
so is the sine of the course A	22° 30′	9.58284
to the departure BC -	12.25	1.08799

so the ship has made 12.25 miles of departure easterly, or has got so far to the eastward of her meridian. Then for the difference of latitude or northing the ship has made, we have (by rectangular trigonometry) the following analogy, viz.

As radius - - - - - -		10.00000
is the distance AC -	32	1.50515
so is the co-sine of course A	22° 30′	9.58284
to the difference of lat. AB	29.57	1.47077

so the ship has differed her latitude, or made of northing, 29.57 minutes.

And since her former latitude was north, and her difference of latitude also north; therefore,

To the latitude sailed from -	30°, 25′ N
add the difference of latitude	00°, 29.57
and the sum is the latitude come to	30°, 54.57′N.

By this case are calculated the tables of difference of latitude, and departure, to every degree, point, and quarter-point, of the compass.

Case II. Course and difference of latitude given, to find distance and departure.

Example. Suppose a ship in the latitude of 45° 25′ north, sails NEbN½ easterly (Plate Navigation, fig. 4), till she comes to the latitude of 46° 55′ north: required the distance and departure made good upon that course.

Since both latitudes are northerly, and the course also northerly; therefore,

From the latitude come to -	46°, 55′
subtract the latitude sailed from	45°, 25′
and there remains - - -	01°, 30′
the difference of latitude, equal to	90 miles.

And (by rectangular trigonometry) we have the following analogy for finding the departure BD, viz.

As radius - - - - - -		10.00000
is to the diff. of latitude AB	90	1.95424
so is the tangent of course A	39°, 22′	9.91404
to the departure BD -	73.84	1.86828

so the ship has got 73.84 miles to the eastward of her former meridian.

Again, for the distance AD, we have (by rectangular trigonometry) the following proportion, viz.

As radius - - - - -		10.00000
is to the secant of the course	39°, 22′	10.11176
so is the diff. of latitude AB	90	1.95424
to the distance AD -	116.4	2.06600

Case III. Difference of latitude and distance given, to find course and departure.

Example. Suppose a ship sails from the latitude of 56° 50′ north, on a rhumb between south and west, 126 miles, and she is then found by observation to be in the latitude of 55°, 40′ north: required the course she sailed on, and her departure from the meridian. (Fig. 5.)

Since the latitudes are both north, and the ship sailing towards the equator; therefore,

From the latitude sailed from -	56°, 50′
subtract the observed latitude -	55°, 10′
and the remainder - - -	01°, 40′

equal to 70 miles, is the difference of latitude.

By rectangular trigonometry we have the following proportion for finding the angle of the course F, viz.

As the distance sailed DF	126	2.10037
is to radius - - - -		10.00000
so is the diff. of latitude FD	70	1.84510
to the co-sine of the course F	56°, 15′	9.74473

which, because she sails between south and west, will be south 56° 15′ west, or SWbW. Then, for the departure, we have (by rectangular trigonometry) the following proportion, viz.

As radius - - - - - -		10.00000
is to the distance sailed DF	126	2.10037
so is the sine of the course F	56°, 15′	9.91985
to the departure DE -	104.8	2.02022

consequently she has made 104.8 miles of departure westerly.

Case IV. Difference of latitude and departure given, to find course and distance.

Example. Suppose a ship sails from the latitude of 44° 50′ north, between south and east, till she has made 64 miles of easting, and is then found by observation to be in the latitude of 42° 56′ north: required the course and distance made good.

Since the latitudes are both north, and the ship sailing towards the equator; therefore,

From the latitude sailed from -	44°, 50′ N
take the latitude come to -	42°, 56′
and there remains - - - -	01°, 54′

equal to 114 miles, the difference of latitude or southing.

In this case (by rectangular trigonometry) we have the following proportion to find the course KGL (fig. 6), viz.

As the diff. of latitude GK	114	2.05690
is to radius - - - -		10.00000
so is the departure KL	64	1.80618
to the tangent of course G	29°, 19′	9.74928

which, because the ship is sailing between south and east, will be south 29° 19′ east, or SSE½ east nearly.

Then for the distance, we shall have (by rectangular trigonometry) the following analogy, viz.

As radius - - - - - -		10.00000
is to the diff. of latitude GK	114	2.05690
so is the secant of the course	29°, 19′	10.05952
to the distance GL -	130.8	2.11642

consequently the ship has sailed on a SSE½ east course 130.8 miles.

Case V. Distance and departure given, to find course and difference of latitude.

Example. Suppose a ship at sea sails from the latitude of 34° 24′ north, between north and west, 124 miles, and is found to have made of westing 86 miles: required the course steered, and the difference of latitude or northing made good.

In this case (by rectangular trigonometry) we have the following proportion for finding the course ADB, (fig. 7), viz.

As the distance AD -	124	2.09342
is to radius - - - -		10.00000
so is the departure AB	86	1.93450
to the sine of the course D	43° 54′	9.84108

so the ship's course is north 33° 45′ west, or NWbN ¼ west nearly.

Then for the difference of latitude, we have (by rectangular trigonometry) the following analogy, viz.

As radius - - - - -		10.00000
is to the distance AD	124	2.09342
so is the co-sine of the course	43°, 54′	9.85766
to the diff. of latitude BD	89.35	1.95108

which is equal to 1 degree and 29 min. nearly.

Hence, to find the latitude the ship is in, since both latitudes are north and the ship sailing from the equator; therefore

To the latitude sailed from -	34°, 24′
add the difference of latitude -	1°, 29′
the sum is - - - -	35°, 53′

the latitude the ship is in north.

Case VI. Course and departure given, to find distance and difference of latitude.

Example. Suppose a ship at sea, in the latitude of 24° 30′ south, sails SEbS, till she has made of easting 96 miles: required the distance and difference of latitude made good on that course.

In this case (by rectangular trigonometry and by case 2,) we have the following proportion for finding the distance (fig. 8), viz.

As the sine of the course G	33°, 45′	9.74474
is to the departure HM	96	1.98227
so is radius - - - -		10.00000
to the distance GM -	172.8	2.23753

Then, for the difference of latitude, we have (by rectangular trigonomety) the following analogy, viz.

As the tangent of course	33°, 45′	9.82489
is to the departure HM	96 -	1.98227
so is radius - - - -		10.00000
to the difference of lat. GH	143.7	2.15738

equal to 2°, 24′ nearly. Consequently, since the latitude the ship sailed from was south, and she sailing still towards the south,

To the latitude sailed from -	24°, 30′
add the difference of latitude -	2°, 25′
and the sum - - -	26°, 55′

is the latitude she is come to south.

6. When a ship sails on several courses in 24 hours, the reducing all these into one, and thereby finding the course and distance made good upon the whole, is commonly called the resolving of a traverse.

7. At sea they commonly begin each day's reckoning from the noon of that day, and from that time they set down all the different courses and distances sailed by the ship till noon next day upon the log-board; then from these several courses and distances, they compute the difference of latitude and departure for each course (by Case I. of Plane Sailing); and these, together with the courses and distances, are set down in a table, called the Traverse Table, which consists of five columns: in the first of which are placed the courses and distances; in the two next, the differences of latitude belonging to these courses, according as they are north or south; and in the two last are placed the departures belonging to these courses, according as they are east or west. Then they sum up all the northings and all the southings; and taking the difference of these, they know the difference of latitude made good by the ship in the last 24 hours, which will be north or south, according as the sum of the northings or southings is greatest: the same way, by taking the sum of all the eastings, and likewise of all the westings, and subtracting the lesser of these from the greater, the difference will be the departure made good by the ship last 24 hours, which will be east or west according as the sum of the eastings is greater or less than the sum of the westings; then from the difference of latitude and departure made good by the ship last 24 hours, found as above, they find the true course and distance made good upon the whole (by Case 4 of Plane Sailing) as also the course and distance to the intended port

Example. Suppose a ship at sea, in the latitude of 48° 24′ north, at noon any day, is bound to a port in the latitude of 43° 40′ north, whose departure from the ship is 144 miles east; consequently the direct course and distance of the ship is SSE. ¼ east 315 miles; but by reason of the shifting of the winds she is obliged to steer the following courses till noon next day, viz. SEbS 56 miles, SSE 64 miles, NWbW 48 miles, SbW $\frac{1}{2}$ west 54 miles, and SEbS $\frac{1}{2}$ east 74 miles: required the course and distance made good the last 24 hours, and the bearing and distance of the ship from the intended port.

The solution of this traverse depends entirely on the 1st and 4th Cases of Plane Sailing; and first we must (by Case 1.) find the difference of latitude and departure for each course. Thus,

1. Course SEbS distance 56 miles.

For departure.

As radius - - -		10 00000
is to the distance -	56	1.74819
so is the sine of the course	33°, 45′	9.74474
to the departure -	31.11	1.49293

For difference of latitude.

As radius - - -		10.00000
is to the distance -	56	1.74819
so is the co-sine of the course	33°, 45′	9.91985
to the diff of latitude	46.57	1.66804

2. Course SSE and distance 64 miles.

For departure.

As radius - - -		10.00000
is to the distance -	64	1.80618
so is the sine of the course	22°, 30′	2.58284
to the departure -	24.5	1.38902

For difference of latitude.

As radius - - -		10 00000
is to the distance -	64	1.80618
so is the co-sine of the course	22°, 30′	9.96562
to the difference of latitude	59.13	1.77180

3. Course NWbW and distance 48 miles.

For departure.

As radius - - -		10.00000
is to the distance -	48	1.68124
so is the sine of the course	56°, 15′	9.91985
to the departure -	39.91	1.60109

For difference of latitude.

As radius - - -		10.00000
is to the distance -	48	1.68124
so is the co-sine of the course	56°, 15′	9.74474
to the difference of latitude	26.67	1.42598

4. Course SbW $\frac{1}{2}$ west and distance 54 miles.

For departure.

As radius - - -		10.00000
is to the distance -	54	1.73239
so is the sine of the course	16°, 52′	9.46262
to the departure -	15.67	8.19501

For difference of latitude.

As radius - - -		10.00000
is to the distance -	54	1.73239
so is the co-sine of the course	16°, 52′	9.98090
to the difference of latitude	51.67	1.71329

5. Course SEbS $\frac{1}{2}$ east and distance 74 miles.

For departure.

As radius - - -		10.00000
is to the distance -	74	1.86923
so is the sine of the course	39°, 22′	9.80228
to the departure -	46.94	1.67151

For difference of latitude.

As radius - - -		10.00000
is to the distance -	74	1.80923
so is the co-sine of the course	39°, 22′	9.88824
to the difference of latitude	57.21	1.75747

Now these several courses and distances, together with the differences of latitude and departures deduced from them, being set down in the proper columns in the traverse table, will stand as follow:

THE TRAVERSE TABLE.

Courses.		*Distances.*	*Diff. of Lat.*		*Departure.*	
			N.	S.	E.	W.
SE b S	—	56	—	46.57	31.11	—
S SE	—	64	—	59.13	24.5	—
NW b W	—	48	26.67	—	—	39.91
SbW $\frac{1}{2}$W	—	54	—	51.67	—	15.67
SEbS $\frac{1}{2}$E	—	94	—	57.21	46.94	—
			26.67	214. 2	108.55	55 58
				26.67	55.58	
		Diff. of Lat.		187.91	46.97	Dep.

From the above table it is plain, since the sum of the northings is 26.67, and of the southings 214.58, the difference between these, viz. 187.91, will be the southing made good by the ship the last 24 hours; also the sum of the eastings being 102.55, and of the westings 55.58, the difference 46.97 will be the easting or departure made good by the ship's last 24 hours; consequently, to find the true course and distance made good by the ship in that time, it will be (by Case 4. of Plane Sailing),

As the difference of latitude	187.91	2.27393
is to the radius - -		10.00000
so is the departure -	46.97	1.67182
to the tangent of the course	14°, 03′	9.39789

which is SbE $\frac{1}{4}$ east nearly. Then for the distance, it will be,

As radius - - - - -		10.00000
is to the difference of latitude	187.91	2.27393
so is the secant of the course	14°, 03′	10.01319
to the distance -	193.7	2.28712

consequently the ship has made good the last 24 hours, on a SbE $\frac{1}{4}$ east course, 193.7 miles: and since the ship is sailing towards the equator; therefore,

From the latitude sailed from -	48°, 24′ N
take the diff. of latitude made good	3 , 08 S
there remains - -	45 , 16 N

the latitude the ship is in north. And because the port the ship is bound for lies in the latitude of 43° 40′ N. and consequently south of the ship; therefore,

From the latitude the ship is in	44°, 16′ N
take the latitude she is bound for	43 , 40 N
and there remains - - -	1 , 36

or 96 miles, the difference of latitude or southing the ship has to make. Again, the whole easting the ship had to make being 144 miles, and she having already made 46.97, or 47 miles of easting; therefore the departure or easting she still has to make will be 97 miles: consequently, to find the direct course and distance between the ship and the intended port, it will be (by Case 4. of Plane Sailing),

As the difference of latitude	96	1.98227
is to radius - - -		10.00000
so is the departure -	97	1.98677
to the tangent of the course	45°, 19′	10.00450

And

As radius - - -		10.00000
is to the difference of latitude	96	1.98227
so is the secant of the course	45°, 19′	10.15293
to the distance - -	136.5	2.13620

whence the true bearing and distance of the intended port is, SE 136.5 miles.

Of Parallel Sailing. Since the parallels of latitude do always decrease the nearer they approach the pole, it is plain a degree on any of them must be less than a degree upon the equator. Now in order to know the length of a degree on any of them, let PB (fig. 9) represent half the earth's axis, PA a quadrant of a meridian, and consequently A a point on the equator, C a point on the meridian, and CD a perpendicular from that point upon the axis, which plainly will be the sine of CP the distance of that point from the pole, or the co-sine of CA its distance from the equator; and CD will be to AB, as the sine of CP, or co-sine of CA, is to the radius. Again, if the quadrant PAB is turned round upon the axis PB, it is plain the point A will describe the circumference of the equator whose radius is AB, and any other point C upon the meridian will describe the circumference of a parallel whose radius is CD.

Cor. 1. Hence (because the circumference of circles are as their radii) it follows, that the circumference of any parallel is to the circumference of the equator, as the co-sine of its latitude is to radius.

Cor. 2. And since the wholes are as their similar parts, it will be, As the length of a degree on any parallel, is to the length of a degree upon the equator, so is the co-sine of the latitude of that parallel, to radius.

Cor. 3. Hence, As radius, is to the co-sine of any latitude, so are the minutes of difference of longitude between two meridians, or their distance in miles upon the equator, to the distance of these two meridians on the parallel in miles.

Cor. 4. And, As the co-sine of any parallel, is to radius, so is the length of any arch on that parallel (intercepted between two meridians) in miles, to the length of a similar arch on the equator, or minutes of difference of longitude.

Cor. 5. Also, As the co-sine of any one parallel, is to the co-sine of any other parallel, so is the length of any arch on the first in miles, to the length of the same arch on the other in miles.

From what has been said, arises the solution of the several cases of parallel sailing, which are as follow:

CASE I. Given the difference of longitude between two places, both lying on the same parallel; to find the distance between those places.

Example 1. Suppose a ship in the latitude of 54° 20′ north, sails directly west on that parallel till she has differed her longitude 12° 45′; required the distance sailed on that parallel.

First, The difference of longitude reduced into minutes, or nautical miles, is 765′, which is the distance between the meridian sailed from, and the meridian come to, upon the equator; then to find the distance between these meridians on the parallel of 54° 20′, or the distance sailed, it will be, by Cor. 3. of the last article,

As radius - - -		10.00000
is to the co-sine of the lat.	54° 20′	9.76572
so are the minutes of diff. lon.	765	2.18366
to the distance on the parallel	446.1	2.64938

Example 2. A degree on the equator being 60 minutes or nautical miles; required the length of a degree on the parallel of 51° 32′.

By Cor. 3. of the last article, it will be

As radius - - -		10.00000
is to the co-sine of the latitude	51°, 32′	9.79383
so are the min. in 1° on the equa.	60	1.77815
to - - -	37.32	1.57198

the miles answering to a degree on the parallel of 51° 32′.

By this problem a table is constructed, shewing the geographic miles answering to a degree on any parallel of latitude; in which you may observe, that the columns marked at the top with D. L. contain the degrees of latitude belonging to each parallel: and the adjacent columns marked at the top Miles, contain the geographic miles answering to a degree upon these parallels. See the table in the article MAP.

Though the table does only shew the miles answering to a degree of any parallel, whose latitude consists of a whole number of degrees; yet it may be made to serve for any parallel whose latitude is some number of degrees and minutes, by making the following proportion, viz.

As 1 degree, or 60 minutes, is to the difference between the miles answering to a degree in the next greater and next less tabular latitude than that proposed; so is the excess of the proposed latitude above the next tabular latitude, to a proportional part; which, subtracted from the miles answering to a degree of longitude in the next less tabular latitude, will give the miles answering to a degree in the proposed latitude.

Example. Required to find the miles answering to a degree on the parallel of 56° 44′.

First, The next less parallel of latitude in the table than that proposed, is that of 56°, a degree of which (by the table) is equal to 35.55 miles; and the next greater parallel of latitude in the table, than that proposed, is that of 57°, a degree of which is (by the table) equal to 32.68 miles; the difference of these is 87, and the distance between these parallels is 1 degree, or 60 minutes; also the distance between the parallel of 56°, and the proposed parallel of 56° 44′, is 44 minutes: then, by the preceding proportion, it will be, As 60 is to 87, so is 44 to 638, the difference between a degree on the parallel of 56° and a degree on the parallel of 56° 44′; which, therefore, taken from 33.55, the miles answering to a degree on the parallel of 56°, leaves 32 912, the miles answering to a degree on the parallel of 56° 44′, as was required.

Case II. The distance sailed in any parallel of latitude, or the distance between any two places on that parallel, being given; to find the difference of longitude.

Example. Suppose a ship in the latitude of 55° 36′ north, sails directly east 685,6 miles: required how much she has differed her longitude.

By Cor. 4. Art. 1. of this section, it will be

As the co-sine of the lat.	55° 36′	9.75202
is to radius - - -		10.00000
so is the distance sailed	685.6	2.83607
to minute of difference of lon.	1213	3.08405

which reduced into degrees, by dividing by 60, makes 20° 13′, the difference of longitude the ship has made.

This also may be solved by help of the preceding table, viz. by finding from it the miles answering to a degree on the proposed parallel, and dividing with this the given number of miles, the quotient will be the degrees and minutes of difference of longitude required.

Thus in the last example, we find, from the foregoing table, that a degree on the parallel of 55° 36′ is equal to 33.89 miles; by this we divide the proposed number of miles 685.6, and the quotient is 20.13 degrees, *i. e.* 20° 13′, the difference of longitude required.

Case III. The difference of longitude between two places on the same parallel, and the distance between them, being given; to find the latitude of that parallel.

Example. Suppose a ship sails on a certain parallel directly west 624 miles, and then has differed her longitude 18° 46′, or 1126 miles: required the latitude of the parallel she sailed upon; it will be by Cor. 3. before

As the min. of diff. long. 1.	126	3.05154
is to the distance sailed	624	2.79518
so is radius - - -		10.00000
to the co-sine of the lat.	56°, 21′	9.74364

consequently the latitude of the ship, or parallel she sailed upon, was 56° 21′.

From what has been said, may be solved the following problems:

Prob. I. Suppose two ships in the latitude of 46° 30′ north, distant asunder 654 miles, sail both directly north 256 miles, and consequently are come to the latitude of 50° 46′ north: required their distance on that parallel.

By Cor. 5. Art. 1. of this section, it will be,

As the co-sine of	46°, 30′	9 83781
is to the co-sine of	50°, 46′	9.80105
so is - -	654 -	2.81558
to - -	601 -	2.77882

the distance between the ships when on the parallel of 50° 46′.

Prob. II. Suppose two ships in the latitude of 45° 48′ north, distant 846 miles, sail directly north till the distance between them is 624 miles: required the latitude come to, and the distance sailed.

By Cor. 5. Art. 1. of this section, it will be,

As their first distance	846	2.92737
is to their second distance	624	2.79518
so is the co-sine of -	45°, 48′	9.84334
to the co-sine - -	59°, 04′	9.71115

the latitude of the parallel the ships are come to.

Consequently, to find their distance sailed,

From the latitude come to -	59°, 04′
subtract the latitude sailed from	45 , 48
and there remains - -	13 , 16

equal to 796 miles, the difference of latitude or distance sailed.

Of Middle-latitude Sailing. 1. When two places lie both on the same parallel, we have shewn how, from the difference of longitude given, to find the miles of easting or westing between them, *et è contra*. But when two places lie not on the same parallel, then their difference of longitude cannot be reduced to miles of easting or westing on the parallel of either place: for if counted on the parallel of that place that has the greatest latitude, it would be too small; and if on the parallel of that place having the least latitude, it would be too great. Hence the common way of reducing the difference of longitude between two places, lying on different parallels, to miles of easting or westing, *et è contra*, is by counting it on the middle parallel between the places, which is found by adding the latitudes of the two places together, and taking half the sum, which will be the latitude of the middle parallel required. And hence arises the solution of the following cases:

Case I. The latitudes of two places, and their difference of longitude, given; to find the direct course and distance.

Example. Required the direct course and distance between the Lizard in the latitude of 50° 0′ north, and longitude of 5° 14′ west, and St. Vincent in the latitude of 17° 10′ N. and longitude of 24° 20′ W.

First, To the latitude of the Lizard	50° 00′	N
add the latitude of St. Vincent	17 10	
The sum is - - - -	67 10	
Half the sum or latitude of the middle parallel is - -	33 35	N
Also the difference of latitude is	33 50	

equal to 1970 miles of southing. Again,

From the longitude of St. Vincent	24 20	W
take the longitude of the Lizard	05 14	
there remains - - - -	16 06	

equal to 1146 min. of diff. of lon. west.

Then for the miles of westing, or departure, it will be (by Case 1. of Parallel Sailing),

As radius - - -		10.00000
is to the co-sine of the middle parallel	33°, 35′	9.92069
so is min. diff. of lon. -	1146	3.05918
to the miles of westing	954.7	2.97987

And for the course it will be (by Case 4. of Plane Sailing),

As the diff. of lat. -	1970	3.29447
is to radius - - - -		10.00000
so is the departure -	954.7	2.97987
to the tang. of the course	25°, 51′	9.68540

which, because it is between south and west, will be SSW $\frac{1}{4}$ west nearly.

For the distance, it will be, by the same case,

As radius - - - -		10.00000
is to the diff. of lat. -	1970	3.29447
so is the secant of the course	25°, 51′	10.04579
to the distance - -	2189	3.34026

whence the direct course and distance from the Lizard to St. Vincent are SSW $\frac{1}{4}$ 2189 W. miles.

Case II. One latitude, course, and distance sailed, being given; to find the other latitude, and difference of longitude.

Example. Suppose a ship in the latitude of 50° 00′ north, sails south 50° 06′ west, 150 miles; required the latitude the ship has come to, and how much she has differed her longitude.

First, For the difference of latitude, it will be, (by Case 1. of Plane Sailing,)

As radius - - -		10.00000
is to the distance -	150	2 17609
so is the co-sine of the course	50°, 06′	9.80716
to the diff. of latitude -	96.22	1.98325

equal to 1°, 36′. And since the ship is sailing towards the equator: therefore,

From the latitude she was in -	50°, 00′
take the difference of latitude -	1 , 36
and there remains - -	48 , 24

the latitude she has come to north. Consequently the latitude of the middle parallel will be 49° 12′.

Then for departure or westing it will be, by the same Case,

As radius - - - - -		10.00000
is to the distance -	150	2.17609
so is the sine of the course	50°, 06′	9.88489
to the departure -	115.1	2.06098

As for the difference of longitude, it will be, (by Case 2. of Plane Sailing,)

As the co-s. of the middle par.	49° 12′	9.81519
is to radius - - - -		10.00000
so is the departure -	115.1	2.06098
to the min. diff. of longitude	176.1	2.24579

equal to 2° 56′, which is the difference of longitude the ship has made westerly.

Case III. Course and difference of latitude given; to find the distance sailed, and difference of longitude.

Example. Suppose a ship in the latitude of 53° 34′ north, sails SE*b*S, till by observation she is found to be in the latitude of 51° 12′, and consequently has differed her latitude 2° 22′, or 142 miles: required the distance sailed, and the difference of longitude.

First, for the departure, it will be, (by Case 2. of Plane Sailing,)

As radius - - -		10 00000
is to the diff. of latitude	142	2.15229
so is the tang. of course	33°, 45′	9.82489
to the departure -	94.88	1.97718

And for the distance it will be, (by the same Case,)

As radius - -		10.00000
is to the diff. of latitude	142	2.15229
so is the secant of the course	33°, 45′	10.08015
to the distance -	170,8	2.23244

Then, since the latitude sailed from was 53° 34′ north, and the latitude come to 51° 12′ north; therefore the middle parallel will be 52° 23′; and consequently, for the difference of longitude, it will be, (by Case 2. of Parallel Sailing,)

As the co-sine of the mid. par.	52°, 23′	9.78560
is to the departure -	94.88	1.97718
so is radius - -		10.00000
to min. of diff. of longitude	155.5	2.19158

equal to 2° 35′, the difference of longitude easterly.

Case IV. Difference of latitude and distance sailed, given; to find the course and difference of longitude.

Example. Suppose a ship in the latitude of 43° 26′ north, sails between south and east, 246 miles, and then is found by observation to be in the latitude of 41° 06′ north: required the direct course and difference of longitude.

First, for the course, it will be, (by Case 3. of Plane Sailing,)

As the distance -	246	2.39094
is to radius - -		10.00000
so is the diff. of latitude	140	2.14613
to the co-sine of the course	55°, 19′	9.75519

which, because the ship sails between south and east, will be south 55° 19′ east, or SE*b*E nearly.

Then, for departure, it will be, by the same Case,

As radius - - -		10.00000
is to the distance -	246	2.39094
so is the sine of the course	55°, 19′	9.91504
to the departure -	202.3	2.30598

Lastly, For the difference of longitude, it will be, (by Case 2. of Parallel Sailing,)

As the co-sine of the mid. par.	42°, 16′	9.86924
is to the departure -	203.8	2.30598
so is radius - -		10 00000
to min. of diff. of longitude	273.3	2.43674

equal to 4° $33'$, the difference of longitude easterly.

CASE V. Course and departure given; to find difference of latitude, difference of longitude, and distance sailed.

Example. Suppose a ship in the latitude of 48° $23'$ north, sails SW*b*S, till she has made of westing 123 miles: required the latitude come to, the difference of longitude, and the distance sailed.

First, For the distance, it will be, (by Case 6. of Plane Sailing,)

As the sine of the course	33°, $45'$	6.74474
is to the departure -	123	2.08991
so is radius - - -		10.00000
to the distance -	221.4	2.34517

And for the difference of latitude, it will be, by the same Case,

As the tang. of course	33°, $45'$	9.82489
is to the departure -	123	2.08991
so is radius - - -		10.00000
to the diff. of latitude	184	2.26502

equal to 3° $04'$; and since the ship is sailing towards the equator, the latitude come to will be 45° $19'$ north; and consequently the middle parallel will be 46° $51'$.

Then, to find the difference of longitude, it will be, (Case 2. of Parallel Sailing,)

As the co-sine of middle par.	46°, $51'$	9.83500
is to the departure -	123	2.08991
so is radius - - -		10.00000
to min. of diff. of longitude	180	2.25491

which is equal to 3° $00'$, the difference of longitude westerly.

CASE VI. Difference of latitude and departure given; to find course, distance, and difference of longitude.

Example. Suppose a ship in the latitude of 46° $37'$ north, sails between south and east, till she has made of easting 146 miles, and is then found by observation to be in the latitude of 43° $24'$ north: required the course, distance, and difference of longitude.

First, by Case 4. of Plane Sailing, it will be for the course,

As the diff. of latitude	193	2.28556
is to the departure -	146	2.16137
so is radius - -		10.00000
to the tang. of the course	36°, $55'$	9.87581

which, because the ship is sailing between south and east, will be south 36° $55'$ east, or SE*b*S $\frac{1}{4}$ east nearly.

For the distance, it will be, by the same Case,

As radius - -		10.00000
is to the diff. of latitude	193	2.28556
so is the secant of the course	36°, $55'$	10.09718
to the distance -	241.4	2.38274

Then, for the difference of longitude, it will be, by Case 2. of Parallel Sailing,

As the co-sine of the mid. par.	45°, $00'$	9.84949
is to the departure -	146	2.16137
so is radius - -		10.00000
to min. of diff. of longitude	205	2.31188

equal to 3° $25'$, the difference of longitude easterly.

CASE VII. Distance and departure given; to find difference of latitude, course, and difference of longitude.

Example. Suppose a ship in the latitude of 33° $40'$ north, sails between south and east 165 miles, and has then made of easting 112.5 miles: required the difference of latitude, course, and difference of longitude.

First, for the course, it will be, by Case 5. of Plane Sailing,

As the distance -	165	2.21748
is to radius - -		10.00000
so is the departure -	102.5	2.05115
to the sine of the course	42°, $59'$	9.83367

which, because the ship sails between south and east, will be south 42° $59'$ east, or SE*b*E $\frac{3}{4}$ east nearly.

And for the difference of latitude, it will be, by the same Case,

As radius - -		10.00000
is to the distance -	165	2.21748
so is the co-sine of the course	42° $59'$	9.86436
to the difference of latitude	120.7	2.08184

equal to 2° $00'$; consequently the latitude come to will be 31° $40'$ north, and the latitude of the middle parallel will be 32° $40'$. Hence, to find the difference of longitude, it will be, by Case 2. of Parallel Sailing,

As the co-sine of the mid. par.	32°, $40'$	9.92522
is to the departure -	112.5	2.05115
so is radius - - -		10.00000
to min. of diff. of long.	133.6	2.12593

equal to 2° $13'$ nearly, the difference of longitude easterly.

CASE VIII. Difference of longitude and departure given: to find difference of latitude, course, and distance sailed.

Example. Suppose a ship in the latitude of 50° $46'$ north, sails between south and west, till her difference of longitude is 3° $12'$, and is then found to have departed from her former meridian 126 miles: required the difference of latitude, course, and distance sailed.

First, for the latitude she has come to, it will be, by Case 3. of Parallel Sailing,

As min. of diff. of long.	192	2.28330
is to the departure -	126	2.10037
so is radius - -		10.00000
to the co-sine of mid. par.	48°, $59'$	9.81707

Now, since the middle latitude is equal to half the sum of the two latitudes (by art. 1. of this sect.) and so the sum of the two latitudes equal to double the middle latitude; it follows, that if from double the middle latitude we subtract any one of the latitudes, the remainder will be the other. Hence from twice 48° $59'$, viz. 97° $58'$, taking 50° $46'$ the latitude sailed from, there remains 47° $12'$ the latitude come to; consequently the difference of latitude is 3° $34'$, or 214 minutes.

Then, for the course, it will be, by Case 4. of Plane Sailing,

As difference of latitude	214	2.33041
is to radius - - -		10.00000
so is the departure -	126	2.10037
to the tang. of the course	30° $29'$	9.76996

which, because it is between south and west, will be south 30° $29'$ west, or SSW $\frac{3}{4}$ west nearly.

And for the distance, it will be, by the same Case,

As radius - - -		10.00000
is to the difference of lat.	214	2.33041
so is the secant of the course	30°, $29'$	10.06461
to the distance - -	248.4	2.39502

2. From what has been said, it will be easy to solve a traverse by the rules of Middle-latitude Sailing.

Example. Suppose a ship in the latitude of 43° $25'$ north, sails upon the following courses, viz. SW*b*S 63 miles, SSW $\frac{1}{2}$ west 45 miles, S*b*E 54 miles, and SW*b*W 74 miles: required the latitude the ship has come to, and how far she has differed her longitude.

First, By Case 2. of this sect. find the difference of latitude and difference of longitude belonging to each course and distance, and they will stand as in the following table:

Courses.	*Distances.*	*Diff. of Lat.* North.	*Diff. of Lat.* South.	*Diff. of Long.* East.	*Diff. of Long.* West.
SW*b*S	- 63	—	52.4	—	47.85
SSW$\frac{1}{2}$W	- 45	—	39.7	—	28.62
S*b*E	- 54	—	53.0	14.75	—
SW*b*W	- 74	—	41.1	—	81.08
					157.55
		Diff. of Lat.	186.2		13.75
				Diff. of Long.	143.80

Hence it is plain the ship has differed her latitude 186.2 minutes, or 3° $6'$, and so has come to the latitude of 40° $19'$ north, and has made of difference of longitude 143.8 minutes, or 2° $23'$ $48''$, westerly.

3. This method of sailing, though it is not strictly true, yet comes very near the truth, as will be evident by comparing an example wrought by this method with the same wrought by the method delivered in the next section, which is strictly true; and it serves, without any considerable error, in runnings of 450 miles between the equator and parallel of 30 degrees, of 300 miles between that and the parallel of 60 degrees, and of 150 miles as far as there is any occasion, and consequently must be sufficiently exact for 24 hours run.

Of Mercator's sailing. Though the meridians do all meet at the pole, and the parallels to the equator do continually decrease, and that in proportion to the co-sines of their latitudes; yet in old sea-charts the meridians were drawn parallel to one another, and consequently the parallels of latitude made equal to the equator, and so a degree of longitude on any parallel as large as a degree on the equator; also in these charts the degrees of latitude were still represented (as they are in themselves) equal to each other, and to those of the equator. By these means the degrees of longitude being increased beyond their just proportion, and the more so the nearer they approach the pole, the degrees of latitude at the same time remaining the same, it is evident places must be very erroneously marked down upon these charts with respect to their latitude and longitude, and consequently their bearing from one another very false.

To remedy this inconvenience, so as still to keep the meridians parallel, it is plain we must protract, or lengthen, the degrees of latitude in the same proportion as those of longitude are, that so the proportion in easting and westing may be the same with that of southing and northing, and consequently the bearings of places from one another are the same upon the chart as upon the globe itself.

Let ABD (fig. 10.) be a quadrant of a meridian, A the pole, D a point on the equator, AC half the axis, B any point upon the meridian, from which draw BF perpendicular to AC, and BG perpendicular to CD: then BG will be the sine, and BF or CG the co-sine, of BD the latitude of the point B; draw DE the tangent and CE the secant of the arch CD. It has been demonstrated, that any arch of a parallel is to the like arch of the equator, as the co-sine of the latitude of that parallel is to radius. Thus any arch, as a minute on the parallel described by the point B, will be to a minute on the equator, as BF or CG is to CD; but since the triangles CGB, CDE, are similar, therefore CG will be to CD as CB is to CE, *i. e.* the co-sine of any parallel is to radius as radius is to the secant of the latitude of that parallel. But it has been just now shown, that the co-sine of any parallel is to radius, as the length of any arch (as a minute) on that parallel is to the length of the like arch on the equator; therefore the length of any arch (as a minute) on any parallel, is to the length of the like arch on the equator, as radius is to the secant of the latitude of that parallel; and so the length of any arch (as a minute) on the equator, is longer than the like arch of any parallel, in the same proportion as the secant of the latitude of that parallel is to radius. But since in this projection the meridians are parallel, and consequently each parallel of latitude equal to the equator, it is plain the length of any arch (as a minute) on any parallel, is increased beyond its just proportion, at such rate as the secant of the latitude of that parallel is greater than radius; and therefore, to keep up the proportion of northing and southing to that of easting and westing, upon this chart, as it is upon the globe itself, the length of a minute upon the meridian at any parallel must also be increased beyond its just proportion at the same rate, *i. e.* as the secant of the latitude of that parallel is greater than radius. Thus to find the length of a minute upon the meridian at the latitude of 75 degrees, since a minute of a meridian is every where equal on the globe, and also equal to a minute upon the equator, let it be represented by unity; then making it as radius to the secant of 75 degrees, so is unity to a fourth number, which is 3.864 nearly; and consequently, by whatever line you represent one minute on the equator of this chart, the length of one minute on the enlarged meridian at the latitude of 75 degrees, or the distance between the parallel of 75° 00′ and the parallel of 75° 01′, will be equal to 3 of these lines, and $\frac{804}{1000}$ of one of them. By making the same proportion, it will be found that the length of a minute on the meridian of this chart at the parallel of 60°, or the distance between the parallel of 60° 00 and that of 60° 01′, is equal to two of these lines. After the same manner, the length of a minute on the enlarged meridian may be found at any latitude; and consequently beginning at the equator, and computing the length of every intermediate minute between that and any parallel, the sum of all these shall be the length of a meridian intercepted between the equator and that parallel; and the distance of each degree and minute of latitude from the equator upon the meridian of this chart, computed in minutes of the equator, forms what is commonly called a table of meridional parts.

If the arch BD (fig. 10.) represents the latitude of any point B, then (CD being radius) CE will be the secant of that latitude; but it has been shown above, that radius is to secant of any latitude, as the length of a minute upon the equator is to the length of a minute on the meridian of this chart at that latitude; therefore CD is to CE, as the length of a minute on the equator is to the length of a minute upon the meridian at the latitude of the point B. Consequently, if the radius CD is taken equal to the length of a minute upon the equator, CE, or the secant of the latitude, will be equal to the length of a minute upon the meridian at that latitude. Therefore, in general, if the length of a minute upon the equator is made radius, the length of a minute upon the enlarged meridian will be every where equal to the secant of the arch contained between it and the equator.

Hence it follows, since the length of every intermediate minute between the equator and any parallel is equal to the secant of the latitude, (the radius being equal to a minute upon the equator), the sum of all these lengths, or the distance of that parallel on the enlarged meridian from the equator, will be equal to the sum of all the secants to every minute contained between it and the equator.

Consequently, the distance between any two parallels on the same side of the equator, is equal to the difference of the sums of all the secants contained between the equator and each parallel; and the distance between any two parallels on contrary sides of the equator, is equal to the sum of the sums of all the secants contained between the equator and each parallel.

By the tables of meridional parts given by all the writers on this subject, may be constructed the nautical chart, commonly called Mercator's chart. See Maps.

In fig. 11, let A and E represent two places upon Mercator's chart, AC the meridian of A, and CE the parallel of latitude passing through E; draw AE, and set off upon AC the length AB equal to the number of minutes contained in the difference of latitude between the two places, and taken from the same scale of equal parts the chart was made by, or from the equator, or any graduated parallel of the chart, and through B draw BD parallel to CE meeting AE in D. Then AC will be the enlarged difference of latitude, AB the proper difference of latitude, CE the difference of longitude, BD the departure, AE the enlarged distance, and AD the proper distance, between the two places A and E; also the angle BAD will be the course, and AE the rhumb-line between them.

Now, since in the triangle ACE, BD is parallel to one of its sides CE; it is plain the triangles ACE, ABD, will be similar, and consequently the sides proportional. Hence arise the solutions of the several cases in this sailing, which are as follow:

Case I. The latitudes of two places given, to find the meridional or enlarged difference of latitude between them.

Of this case there are three varieties, viz. either one of the places lies on the equator: or both on the same side of it; or lastly, on different sides.

1. If one of the proposed places lies on the equator, then the meridional difference of latitude is the same with the latitude of the other place, taken from the table of meridional parts.

Example. Required the meridional difference of latitude between St. Thomas, lying on the equator, and St. Antonio, in the latitude of 17° 20′ north. We look in the tables for the meridional part answering to 17° 20′, and find it to be 1056.2, the enlarged difference of latitude required.

2. If the two proposed places are on the same side of the equator, then the meridional difference of latitude is found by subtracting the meridional parts answering to the least latitude from those answering to the greatest, and the difference is that required.

Example. Required the meridional difference of latitude between the Lizard in the latitude of 50° 00′ north, and Antigua in the latitude of 17° 30′ north.

From the meridional parts of	50°, 00′	3474.5
subtract the merid. parts of	17 30	1066.7
there remains - -		2407.8

the meridional difference of latitude required.

3. If the places lie on different sides of the equator, then the meridional difference of latitude is found by adding together the meridional parts answering to each latitude, and the sum is that required.

Example. Required the meridional difference of latitude between Antigua in the latitude of 17° 30′ north, and Lima in Peru in the latitude of 12° 30′ south.

To the merid. parts answering to	17° 30′	1066.7
add these answering to -	12 30	756.1
the sum is - - - -		1822.8

the meridional difference of latitude required.

Case II. The latitudes and longitudes of two places given; to find the direct course and distance between them.

Example. Required to find the direct course and distance between the Lizard in the latitude of 50° 00′ north, and Port Royal in Jamaica, in the latitude of 17° 40′; differing in longitude 70° 46′, Port Royal lying so far to the westward of the Lizard.

Preparation.

From the latitude of the Lizard -	50° 00′
subtract the latitude of Port Royal	17 40
and there remains - - - -	32 20

equal to 1940 minutes, the proper difference of latitude.

Then from the merid. parts of	50° 00′	3474.5
subtract those of -	17 40	1057.2
and there remains - - -		2397.3

the meridional or enlarged difference of longitude.

Geometrically. Draw the line AC, fig. 12, representing the meridian of the Lizard at A; and set off from A, upon that line, AE equal to 1940 (from any scale of equal parts) the proper difference of latitude, also AC equal to 2397.3 (from the same scale) the meridional or enlarged difference of latitude. Upon the point C raise CB perpendicular to AC, and make CB equal to 4246, the minutes of difference of longitude.

Join AB, and through E draw ED parallel to BC: so the case is constructed; and AD applied to the same scale of equal parts the other legs were taken from, will give the direct distance, and the angle DAD measured by the line of chords will give the course.

By Calculation.

For the angle of the course EAD, it will be, (by rectangular trigonometry,)

AC : CB :: R : T, BAC,

i. e. As the merid. diff. of lat.	2397.3	3.37970
is to the difference of long.	4246.0	3.62798
so is radius - -		10.00000
to the tang. of the direct course	60° 33′	10.34828

which, because Port Royal is southward of the Lizard, and the difference of longitude westerly, will be south 60° 33′ west, or SW*b*W ½ west nearly.

Then for the distance AD, it will be (by rectangular trigonometry),

R : AE :: Sec. A : AD,

i. e. As the radius - -		10.00000
is the proper diff. of lat.	1940	3.28780
so is the secant of the course	60° 33′	10.30833
to the distance -	3945.6	3.59613

consequently the direct course and distance between the Lizard and Port Royal in Jamaica, is south 60° 33′ 3945.6 miles.

Case III. Course and distance sailed, given; to find difference of latitude, and difference of longitude.

Example. Suppose a ship from the Lizard in the latitude of 50° 00′ north, sails south 35° 40′ west 156 miles: required the latitude come to, and how much she has altered her longitude.

Geometrically. 1. Draw the line BK (fig. 13), representing the meridian of the Lizard at B; from B draw the line BM, making with BK an angle equal to 35° 40′ and upon this line set off BM equal to 56 the given distance, and from M let fall the perpendicular MK upon BK.

Then for BK the proper difference of latitude, it will be, (by rectangular trigonometry,)

R : MB :: S. BMK : BK,

i. e. As radius - -		10.00000
is to the distance -	156	2.19312
so is the co-sine of the course	35° 40′	9.90978
to the proper diff. of lat.	127	2.10290

equal to 2° 07′; and since the ship is sailing from a north latitude towards the south, therefore the latitude come to will be 47° 53′ north. Hence the meridional difference of latitude will be 193.4.

2. Produce BK to D, till BD is equal to 193.4; through D draw DL parallel to MK, meeting DM produced in L; then DL will be the difference of longitude: to find which by calculation, it will be, (by rectangular trigonometry,)

R : BD :: T. LBD : DL,

i. e. As radius - -		10.00000
is to the meridional diff. of lat.	193.4	2.28646
so is the tang. of the course	35° 40′	9.85594
to minutes of diff. of long.	138.8	2.14240

equal to 2° 18′ 48″, the difference of longitude the ship has made westerly.

Case IV. Given course and both latitudes, viz. the latitude sailed from, and the latitude come to; to find the distance sailed, and the difference of longitude.

Example. Suppose a ship in the latitude of 50° 20′ north, sails south 33° 45′ east, until by observation she is found to be in the latitude of 51° 45′ north: required the distance sailed, and the difference of longitude.

Geometrically. Draw AB (fig. 14), to represent the meridian of the ship in the first latitude; and set off from A to B 155 the minutes of the proper difference of latitude, also AG equal to 257.9 the minutes of the enlarged difference of latitude. Through B and G, draw the lines BC and GK perpendicular to AG; also draw AK, making with AG an angle of 33° 45′, which will meet the two former lines in the points C and K; so the case is constructed, and AC and GK may be found from the line of equal parts: to find which,

By Calculation;

First, For the difference of longitude, it will be, (by rectangular trigonometry,)

R : AG :: T. GAK : GK,

i. e. As radius - -		10.00000
is to the enlarged diff. of lat.	257.2	2.41145
so is the tang. of the course	33° 45′	9.84289
to min. of diff. of longitude	172.3	2.23634

equal to 2° 52′ 18″, the difference of longitude the ship has made easterly.

This might also have been found, by first finding the departure BC (by Case 2. of Plane Sailing), and then it would be AB : BC :: AG : GK, the difference of longitude required.

Then, for the direct distance AC, it will be, (by rectangular trigonometry,)

R : AB :: Sec. A : AC,

i. e. As radius - -		10.00000
is to the proper diff. of lat.	155	2.19033
so is the secant of the course	33° 45′	10.08015
to the direct distance	186.4	2.27048

consequently the ship has sailed south 33° 45′ east 186.4 miles, and has differed her longitude 2° 52′ 18″ easterly.

Case V. Both latitudes and distances sailed, given; to find the direct course, and difference of longitude.

Example. Suppose a ship from the latitude of 45° 26′ north, sails between north and east 195 miles, and then by observation she is found to be in the latitude of 48° 6′ north: required the direct course, and difference of longitude.

Geometrically. Draw AB (fig. 15), equal to 160, the proper difference of latitude, and from the point B raise the perpendicular BD; then take 195 in your compasses, and setting one foot of them in A, with the other cross the line BD in D. Produce AB, till AC is equal to 233.6 the enlarged difference of latitude. Through C draw CK parallel to BD, meeting AD produced in K: so the case is constructed; and the angle A may be measured by the line of chords, and CK by the line of equal parts: to find which,

By Calculation;

First, For the angle of the course BAD, it will be, (by rectangular trigonometry,)

AB : R :: AD : Sec. A.

i. e. As the proper diff. of lat.	160	2.20412
is to radius - -		10.00000
so is the distance -	195	2.29003
to the secant of the course	34° 52′	10.08591

which, because the ship is sailing between north and east, will be north 34° 52′ east, or NE*b*N 1° 7′ easterly.

Then, for the difference of longitude, it will be, (by rectangular trigonometry,)

R : AC :: T. A : CK,

i. e. As radius - -		10.00000
is to the merid. diff. of lat.	233.6	2.36847
so is the tang. of the course	34° 52′	9.84307
to min. of diff. of longitude	162.8	2.21154

equal to 2° 42′ 48″, the difference of longitude easterly.

Case VI. One latitude, course, and difference of longitude, given; to find the other latitude and distance sailed.

Example. Suppose a ship from the latitude of 48° 50′ north, sails south 34° 40′ west, till her difference of longitude is 2° 42′: required the latitude come to, and the distance sailed.

Geometrically. 1. Draw AE (fig. 16), to represent the meridian of the ship in the first latitude, and make the angle EAC equal to 34° 40′, the angle of the course; then draw FC parallel to AE, at the distance of 164 the minutes of difference of longitude, which will meet AC in the point C. From C let fall upon AE the perpendicular CE; then AE will be the enlarged difference of latitude. To find which, by calculation, it will be, (by rectangular trigonometry,)

T. A : R :: CE : AE,

i. e. As the tang. of the course	34° 40′	9.83984
is to the radius - -		10.00000
so is min. of diff. longitude	164	2.21484
to the enlarged diff. of latitude	237.2	2.37500

and because the ship is sailing from a north latitude southerly, therefore

From the merid. parts of the latitude sailed from	48° 50′	3366.9
take the merid. difference of latitude		237.2
and there remains - - -		3129.7

the meridional parts of the latitude come to, viz. 46° 09′.

Hence, for the proper difference of latitude,

From the latitude sailed from -	48° 50′ N
take the latitude come to - -	46 09 N
and there remains - -	2 41

equal to 161, the minutes of difference of latitude.

2. Set off upon AE the length AD equal to 161 the proper difference of latitude, and through D draw DB parallel to CE: then AB will be the direct distance. To find which, by calculation, it will be, (by rectangular trigonometry,)

R : AD :: Sec. A : AB.

i. e. As radius - -		10.00000
is to the proper diff. of lat.	161	2.20683
so is the secant of the course	34° 40′	10.08488
to the direct distance -	195.8	2.29171

Case VII. One latitude, course, and departure, given; to find the other latitude, distance sailed, and difference of longitude.

Example. Suppose a ship sails from the latitude of 54° 36′ north, south 42° 33′ east, until she has made of departure 116 miles: required the latitude she is in, her direct distance sailed, and how much she has altered her longitude.

Geometrically. 1. Having drawn the meridian AB (fig. 17), make the angle BAD equal to 42° 33′. Draw FD parallel to AB at the distance of 116, which will meet AD in D. Let fall upon AB the perpendicular DB. Then AB will be the proper difference of latitude, and AD the direct distance: to find which by calculation, first, for the distance AD it will be, (by rectangular trigonometry,)

S. A : BD :: R : AD.

i. e. As the sine of the course	42° 33′	9.83010
is to the departure -	116	2.06446
so is radius - -		10.00000
to the direct distance -	171.5	2.23436

Then, for the proper difference of latitude, it will be, (by rectangular trigonometry,)

T. A : BD :: R : AB.

i. e. As the tang. of the course	42° 33′	9.96281
is to the departure -	116	2.06446
so is radius - -		10.00000
to the proper diff. of latitude	126.4	2.10165

equal to 2° 6′: consequently the ship has come to the latitude of 52° 30′ north; and so the meridional difference of latitude will be 212.2.

2. Produce AB to E, till AE be equal to 212.2; and through E draw EC parallel to BD, meeting AD produced in C; then EC will be the difference of longitude; to find which by calculation, it will be, (by rectangular trigonometry,)

R : AE :: T. A : EC.

i. e. As radius - -		10.00000
is to the merid. diff. of lat.	212.2	2.32675
so is the tang. of the course	42° 33′	9.96281
to the min. of diff. of long.	194.8	2.28956

equal to 3° 14′ 48″, the difference of longitude easterly.

This might have been found otherwise, thus: Because the triangles ACE, ADB, are similar; therefore it will be,

AB : BD :: AE : EC.

i. e. As the proper diff. of lat.	126.4	2.10165
is to the departure -	116	2.06446
so is the enlarged diff. of lat.	212.2	2.32675
to min. of diff. of longitude	194.8	2.28956

Case VIII. Both latitudes and departure given; to find course, distance, and difference of longitude.

Example. Suppose a ship from the latitude of 46° 20′ N. sails between south and west, till she has made of departure 126.4 miles; and is then found by observation to be in the latitude of 43° 35′ north: required the course and distance sailed, and difference of longitude.

Geometrically. Draw AK (fig. 18), to represent the meridian of the ship in her first latitude; set off upon it AC, equal to 165, the proper difference of latitude. Draw BC perpendicular to AC, equal to 126.4 the departure, and join AB. Set off from A, AK equal to 233.3, the enlarged difference of latitude; and through K draw KD parallel to BC, meeting AB produced in D; so the case is constructed, and DK will be the difference of longitude, AB the distance, and the angle A the course; to find which,

By Calculation;

First, For DC the difference of longitude, it will be,

AC : CB :: AK : KD.

i. e. As the proper diff. of lat.	165	2.21748
is to the departure -	126.4	2.10175
so is the enlarged diff. of lat.	233.3	2.36791
to min. of diff. of longitude	178.7	2.25218

equal to 2° 58′ 42″, the difference of longitude westerly.

Then, for the course it will be, (by rectangular trigonometry,)

AC : BC :: R : T. A.

i. e. As the proper diff. of lat.	165	2.21748
is to the departure -	446.1	2.10175
so is radius - -		10.00000
to the tang. of the course	37° 27′	9.88427

which, because the ship sails between south and west, will be south 37° 27′ west, or SW*b*S 6° 33′ westerly.

Lastly, For the distance AB, it will be, (by rectangular trigonometry,)

S, A : BC :: R : AB.

i. e. As the sine of the course	37° 27′	9.78395
is to the departure -	126.4	2.10175
so is radius -	-	10.00000
to the direct distance -	207.9	2.31780

Case IX. One latitude, distance sailed, and departure, given; to find the other latitude, difference of longitude, and course.

Example. Suppose a ship in the latitude of 48° 33′ north, sails between south and east 138 miles, and has then made of departure 112.6: required the latitude come to, the direct course, and difference of longitude.

Geometrically. 1. Draw BD (fig. 19) for the meridian of the ship at B; and parallel to it draw FE, at the distance of 112.6, the departure. Take 138, the distance, in your compasses, and fixing one point of them in B, with the other cross the line FE in the point E; then join B and E, and from E let fall upon BD the perpendicular ED; so BD will be the proper difference of latitude, and the angle B will be the course; to find which by calculation,

First, For the course it will be, (by rectangular trigonometry,)

BE : R :: DE : S. B.

i. e. As the distance -	138	2.13988
is to radius - - - -		10.00000
so is the departure -	112.6,	2.05154
to the sine of the course	54° 41′	9.91166

which, because the ship sails between south and east, will be south 54° 41′ east, or SE 0° 41′ easterly.

Then, for the difference of latitude, it will be, (by rectangular trigonometry,)

R : BE :: Co. S. B : BD.

i. e. As radius - - - -		10.00000
is to the distance -	138	2.13988
so is the co-sine of the course	54° 41′	9.76200
to the difference of latitude	79.8	1.90188

equal to 1° 19′. Consequently the ship has come to the latitude of 47° 13′. Hence the meridional difference of latitude will be 117.7.

2dly. Produce B to A, till BA is equal to 117.7; and through A draw AC parallel to DE, meeting BE produced in C; then AC will be the difference of longitude; to find which by calculation, it will be,

BD : DE :: BA : AC.

i. e. As the proper diff. of lat.	79.8	1.90180
is to the departure -	112.6	2.05154
so is the enlarged diff. of lat.	117.7	2.07078
to the diff. of longitude -	166.1	2.22014

equal to 2° 46′ 06″, the difference of longitude easterly.

Having shewn under the article Maps how to construct a Mercator's chart, we shall now proceed to point out its several uses.

Prob. I. Let it be required to lay down a place upon the chart, its latitude, and the difference of longitude between it and some known place upon the chart being given.

Example. Let the known place be the Lizard, lying on the parallel of 50° 00′ north, and the place to be laid down St. Katherine's on the east coast of America, differing in longitude from the Lizard 42° 36′, lying so much to the westward of it.

Let L represent the Lizard on the chart, (fig. 20,) lying on the parallel of 50° 00′ north, its meridian. Set off AE from E upon the equator EQ 42° 36′, towards Q, which will reach from E to F. Through F draw the meridian FG, and this will be the meridian of St. Katharine's then set off from Q to H upon the graduated meridian QB, 28 degrees; and through H draw the parallel of latitude HM, which will meet the former meridian in K, the place upon the chart required.

Prob. II. Given two places upon the chart, to find their difference of latitude and difference of longitude.

Through the two places draw parallels of latitude; then the distance between these parallels, numbered in degrees and minutes upon the graduated meridian, will be the difference of latitude required; and through the two places drawing meridians, the distance between these, counted in degrees and minutes on the equator, or any graduated parallel, will be the difference of longitude required.

Prob. III. To find the bearing of one place from another, upon the chart.

Example. Required the bearing of St. Katherine's at K, from the Lizard at L.

Draw the meridian of the Lizard AE, and join K and L with the right line KL; then, by the line of chords, measuring the angle KLE, and with that entering the tables, we shall have the thing required.

This may also be done, by having compasses drawn on the chart (suppose at two of its corners); then lay the edge of a ruler over the two places, and let fall a perpendicular, or take the nearest distance from the centre of the compass next the first place, to the ruler's edge; then, with this distance in your compasses, slide them along by the ruler's edge, keeping one foot of them close to the ruler, and the other as near as you can judge perpendicular to it, which will describe the rhumb required.

Prob. IV. To find the distance between two given places upon the chart.

This problem admits of four cases, according to the situation of the two places with respect to one another.

Case I. When the given places lie both upon the equator.

In this case their distance is found by converting the degrees of difference of longitude intercepted between them into minutes.

Case II. When the two places lie both on the same meridian.

Draw the parallels of those places; and the degrees upon the graduated meridian, intercepted between those parallels, reduced to minutes, give the distance required.

Case III. When the two places lie on the same parallel.

Example. Required to find the distance between the points K and N, both lying on the parallel of 28° 00′ north. Take from your scale the chord of 60°, or radius, in your compasses, and with that extent on KN as a base make the isosceles triangle KPN: then take from the line of sines the co-sine of the latitude, or sine of 72°, and set that off from P to S and T. Join S and T with the right line ST, and that applied to the graduated equator will give the degrees and minutes upon it equal to the distance; which, converted into minutes, will be the distance required.

The reason of this is evident from the method of Parallel Sailing; for it has been there demonstrated, that radius is to the co-sine of any parallel, as the length of any arch on the equator, to the length of the same arch on that parallel. Now, in this chart KN is the distance of the meridians of the two places K and N upon the equator; and since, in the triangle PNK, ST is the parallel to KN, therefore PN : PT :: NK : TS. Consequently TS will be the distance of the two places K and N upon the parallel of 28°.

If the parallel the two places lie on is not far from the equator, and they not far asunder; then their distance may be found thus: Take the distance between them in your compasses and apply that to the graduated meridian, so that one foot may be as many minutes above as the other is below the given parallel; and the degrees and minutes intercepted, reduced to minutes, will give the distance.

Or it may also be found thus: Take the length of a degree on the meridian at the given parallel, and turn that over on the parallel from the one place to the other, as oft as you can; then, as often as that extent is contained between the places, so many times 60 miles will be contained in the distance between them.

Case IV. When the places differ both in longitude and latitude.

Example. Suppose it was required to find the distance between the two places *a* and *e* upon the chart. By Prob. II. find the difference of latitude between them; and take that in your compasses from the graduated equator, which set off on the meridian of *a*, from *a* to *b*; then through *b* draw *bc* parallel to *de*; and taking *ac* in your compasses, apply it to the graduated equator, and it will shew the degrees and minutes contained in the distance required, which multiplied by 60 will give the miles of distance.

The reason of this is evident; for it is plain *ad* is the enlarged difference of latitude, and *ab* the proper; consequently *ae* is the enlarged distance, and *ac* the proper.

Prob. V. To lay down a place upon the chart, its latitude and bearing from some known place upon the chart being known; or (which is the same) having the course and difference of latitude that a ship has made, to lay down the running of the ship, and find her place upon the chart.

Example. A ship from the Lizard in the latitude of 50° 00′ north, sails SSW till she has differed her latitude 36° 40′: required her place upon the chart.

Count from the Lizard at L, on the graduated meridian downwards (because the course is southerly) 36° 40′ to *g*; through which draw a parallel of latitude, which will be the parallel the ship is in; then from L draw a SSW line L*f*, cutting the former parallel in *f*, and this will be the ship's place upon the chart.

Prob. VI. One latitude, course, and distance sailed, given; to lay down the running of the ship, and find her place upon the chart.

Example. Suppose a ship at *a* in the latitude of 20° 00′ north, sails north 37° 20′, east 191 miles: required the ship's place upon the chart.

Having drawn the meridian and parallel of the place *a*, set off the rhumb-line *ae*, making with *ab* an angle of 37° 20′; and upon it set off 191 from *a* to *c*; through *c* draw the parallel *cb*; and taking *ab* in your compasses, apply it to the graduated equator, and observe the number of degrees it contains; then count the same number of degrees on the graduated meridian from C to *b*, and through *b* draw the parallel *be*, which will cut *ac* produced in the point *e*, the ship's place required.

Prob. VII. Both latitudes and distance sailed given; to find the ship's place upon the chart.

Example. Suppose a ship sails from *a*, in the latitude of 20° 00′ north, between north and east 191 miles, and is then in the latitude of 45° 00′ north: required the ship's place upon the chart.

Draw *de* the parallel of 45°, and set off upon the meridian of *a* upwards, *ab* equal to the proper difference of latitude taken from the equator or graduated parallel. Through *b* draw *bc* parallel to *de*; then, with 191 in your compasses, fixing one foot of them in *a*, with the other cross *bc* in *c*. Join *a* in *c* with the right line *ac*; which produced will meet *de* in *e*, the ship's place required.

Prob. VIII. One latitude, course, and difference of longitude, given; to find the ship's place upon the chart.

Example. Suppose a ship from the Lizard in the latitude of 50° 00′ north, sails SW*b*W, till her difference of longitude is 42° 36′: required the ship's place upon the chart.

Having drawn AE the meridian of the Lizard at L, count from E to F upon the equator 42° 36′; and through F draw the meridian EG; then from L draw the SW*b*W line LK, and where this meets FG, as at K, will be the ship's place required.

Prob. IX. One latitude, course, and departure, given; to find the ship's place upon the chart.

Example. Suppose a ship at *a* in the latitude of 20° 00′ north, sails north 37° 20′ east, till she has made of departure 116 miles: required the ship's place upon the chart.

Having drawn the meridian of *a*, at the distance of 116 draw parallel to it the meridian *kl*. Draw the rhumb-line *ac*, which will meet *kl* in some point *c*; then through *c* draw the parallel *cb*, and *ab* will be the proper difference of latitude, and *bc* the departure. Take *ab* in your compasses, and apply it to the equator or graduated parallel; then observe the number of degrees it contains, and count so many on the graduated meridian from C upwards to *b*. Through *b* draw the parallel *be*, which will meet *ac* produced in some point as *e*, which is the ship's place upon the chart.

Prob. X. One latitude, distance, and departure, given; to find the ship's place upon the chart.

Example. Suppose a ship at *a* in the latitude of 20° 00′ north, sails 191 miles between north and east, and then is found to have made of departure 116 miles: required the ship's place upon the chart.

Having drawn the meridian and parallel of the place *a*, set off upon the parallel *am* equal to 116, and through *m* draw the meridian *kl*. Take the given distance 191 in your compasses; setting one foot of them in *a*, with the other cross *kl* in *c*. Join *ac*, and through *c* draw the parallel *cb*; so *cb* will be the departure, and *ab* the proper difference of latitude; then proceeding with this as in the foregoing problem, you will find the ship's place to be *c*.

Prob. XI. The latitude sailed from, difference of latitude, and departure, given; to find the ship's place upon the chart.

Example. Suppose a ship from *a* in the latitude of 20° 00′ north, sails between north and east, till she is in the latitude of 45° 00′ north, and is then found to have made of departure 116 miles: required the ship's place upon the chart.

Having drawn the meridian of *a*, set off upon it, from *a* to *b*, 25 degrees, (taken from the equator or graduated parallel) the proper difference of latitude; then through *b* draw the parallel *bc*, and make *bc* equal to 116 the departure, and join *ac*. Count from the parallel of *a* on the graduated meridian upwards to *d* 25 degrees, and through *d* draw the parallel *de*, which will meet *ac* produced in some point *e*, and this will be the place of the ship required.

In the article of Plane Sailing, it is evident that the terms meridional distance, departure, and difference of longitude, were synonimous, constantly signifying the same thing; which evidently followed from the supposition of the earth's surface being projected on a plane in which the meridians were made parallel, and the degrees of latitude equal to one another and to those of the equator. But since it has been demonstrated, that if, in the projection of the earth's surface upon a plane, the meridians are made parallel, the degrees of latitude must be unequal, still increasing the nearer they come to the pole; it follows, that these terms must denote lines really different from one another.

Of Oblique Sailing. The questions that may be proposed on this head being innumerable, we shall only give one as a specimen.

Coasting along the shore, I saw a cape bear from me NNE: then I stood away NW*b*W 20 miles, and I observed the same cape to bear from me NE*b*E: required the distance of the ship from the cape at each station.

Geometrically. Draw the circle NWSE (figure 21,) to represent the compass, NS the meridian, and WE the east and west line, and let C be the place of the ship in her first station; then from C set off upon the NW*b*W line, CA 20 miles, and A will be the place of the ship in her second station.

From C draw the NNE line CB, and from A draw AB parallel to the NE*b*E line CD, which will meet CB in B, the place of the cape, and CB will be the distance of it from the ship in its first station, and AB the distance in the second: to find which,

By Calculation;

In the triangle ABC are given AC, equal to 20 miles; the angle ACB, equal to 78° 45′, the distance between the NNE and NW*b*W lines; also the angle ABC, equal to BCD, equal to 33° 45′, the distance between the NNE and NE*b*E lines; and consequently the angle A, equal to 67° 30′.

Hence, for CB, the distance of the cape from the ship in her first station, it will be, (by oblique trigonometry,)

S. ABC : AC :: S. BAC : CB.

i. e. As the sine of the angle B	33° 45′	9.74473
is to the distance run AC	20 —	1.30163
so is the sine of BAC	67 30	9.96562
to CB - - - -	33.26	1.52191

the distance of the cape from the ship at the first station. Then for AB, it will be, (by oblique trigonometry,)

S. ABC : AC :: S. ACB : AB.

i. e. As the sine of B -	33° 45′	9.74474
is to AC - - -	20 —	1 30103
so is the sine of C -	78 45	9.99157
to AB - - -	35.31	1.54786

the distance of the ship from the cape at her second station.

Of the Log-line and Compass. The method commonly made use of for measuring a ship's way at sea, or how far she runs in a given space of time, is by the log-line and half-minute glass. See the article Log.

The log is generally about a quarter of an inch thick, and five or six inches from the angular point to the circumference. It is balanced by a thin plate of lead, nailed upon the arch, so as to swim perpendicularly in the water, with about $\frac{2}{3}$ impressed under the surface. The line is fastened to the log by means of two legs, one of which passes through a hole at the corner and is knotted on the opposite side; while the other leg is attached to the arch by a pin fixed in another hole, so as to draw out occasionally. By these legs the log is hung in equilibrio; and the line which is united to it, is divided into certain spaces, which are in proportion to an equal number of geographical miles, as a half-minute or quarter-minute is to an hour of time.

These spaces are called knots, because at the end of each of them there is a piece of twine with knots in it, inreeved between the strands of the line, which shews how many of these spaces or knots are run out during the half-minute. They commonly begin to be counted at the distance of about 10 fathoms or 60 feet from the log, so that the log when it is hove overboard may be out of the eddy of the ship's wake before they begin to count; and for the more ready discovery of this point of commencement, there is commonly fastened at it a piece of red rag.

The log being thus prepared, and hove overboard from the poop, and the line veered out by help of a reel that turns easily, and about which it is wound as fast as the log will carry it away, or rather as the ship sails from it, will shew, according to the time of veering, how far the ship has run in a given time, and consequently her rate of sailing.

A degree of a meridian according to the exactest measures contains about 69.545 English miles; and each mile by the statute being 5280 feet, therefore a degree of the meridian will be about 7200 feet; whence the $\frac{1}{60}$ of that, viz. a minute or nautical mile, must contain 6120 standard feet; consequently, since $\frac{1}{2}$ is the $\frac{1}{120}$ part of an hour, and each knot is the same part of a nautical mile, it follows, that each knot will contain the $\frac{1}{120}$ of 6120 feet viz. 51 feet.

Hence it is evident, that whatever number of knots the ship runs in half a minute, the same number of miles she will run in one hour, supposing her to run with the same degree of velocity during that time; and therefore it is the general way to heave the log every hour, to know her rate of sailing: but if the force or direction of the wind varies, and not continues the same during the whole hour; or if there has been more sail set, or any sail handed, so that the ship has run swifter or slower in any part of the hour than she did at the time of heaving the log; then there must be an allowance made accordingly for it, and this must be according to the discretion of the artist.

Sometimes, when the ship is before the wind, and there is a great sea setting after her, it will bring home the log, and consequently the ship will sail faster than is given by the log. In this case it is usual, if there is a very great sea, to allow one mile in ten; and less in proportion, if the sea is not so great. But for the generality, the ship's way is really greater than that given by the log; and therefore, in order to have the reckoning rather before than behind the ship (which is the safest way), it will be proper to make the space on the log-line between knot and knot to consist of 50 feet instead of 51.

If the space between knot and knot on the log-line should happen to be too great in proportion to the half-minute glass, viz. greater than 50 feet, then the distance given by the log will be too short; and if that space is too small, then the distance run (given by the log) will be too great: therefore, to find the true distance in either case, having measured the distance between knot and knot, we have the following proportion, viz.

As the true distance, 50 feet, is to the measured distance; so are the miles of distance given by the log, to the true distance in miles that the ship has run.

Example I. Suppose a ship runs at the rate of $6\frac{1}{4}$ knots in half a minute; but measuring the space between knot and knot, I find it to be 56 feet: required the true distance in miles.

Making it, As 50 feet, are to 56 feet, so are 6.25 knots, to seven knots; I find that the true rate of sailing is 7 miles in the hour.

Example II. Suppose a ship runs at the rate of $6\frac{1}{2}$ knots in half a minute; but meaduring the space between knot and knot, I find it to be only 44 feet: required the true rate the ship is sailing.

Making it, As 50 feet are to 44 feet, so are 6.5 knots to 5.72 knots, I find that the true rate of sailing is 5.72 miles in the hour.

Again, supposing the distance between knot and knot on the log-line to be exactly 50 feet, but that the glass is not 30 seconds; then, if the glass requires longer time than 30 seconds, the distance given will be too great, if estimated by allowing one mile for every knot run in the time the glass runs; and, on the contrary, if the glass requires less time to run than 30 seconds, it will give the distance sailed too small. Consequently, to find the true distance in either case, we must measure the time the glass requires to run out (by the method in the following article); then we have the following proportion, viz.

As the number of seconds the glass runs, is to half a minute, or 30 seconds; so is the distance given by the log, to the true distance.

Example I. Suppose a ship runs at the rate of $7\frac{1}{2}$ knots in the time the glass runs; but measuring the glass, I find it runs 34 seconds; required the true distance sailed.

Making it, As 34 seconds are to 30 seconds, so are 7.5 to 6.6; I find that the ship sails at the rate of 6.6 miles an hour.

Example II. Suppose a ship runs at the rate of $6\frac{1}{2}$ knots; but measuring the glass, I find it runs only 25 seconds; required the true rate of sailing.

Make it, As 25 seconds are to 30 seconds, so are 6.5 knots to 7.8 knots; I find that the true rate of sailing is 7.8 miles an hour.

In order to know how many seconds the glass runs, you may try it by a watch or clock that vibrates seconds; but if neither of these is at hand, then take a line, and to the one end fastening a plummet, hang the other upon a nail or peg so that the distance from the peg to the centre of the plummet is $39\frac{1}{6}$ inches: then this put into motion will vibrate seconds; *i. e.* every time it passes the perpendicular, you are to count one second; consequently, by observing the number of vibrations that it makes during the time the glass is running, we know how many seconds the glass runs.

If there is an error both in the log-line and half-minute glass, viz. if the distance between knot and knot and the log-line is either greater or less than 50 feet, and the glass runs either more or less than 30 seconds; then the finding out the ship's true distance will be somewhat more complicate, and admit of three cases, viz.

Case I. If the glass runs more than 30 seconds, and the distance between knot and knot is less than 50 feet, then the distance given by the log-line, viz. by allowing 1 mile for each knot the ship sails while the glass is running, will always be greater than the true distance, since either of these errors gives the distance too great. Consequently, to find the true rate of sailing in this case, we must first find the distance on the supposition that the log-line only is wrong, and then with this we shall find the true distance.

Example. Suppose a ship is found to run at the rate of 6 knots; but examining the glass, I find it runs 35 seconds; and measuring the log-line, I find the distance between knot and knot to be but 46 feet: required the true distance run.

First, we have the following proportion, viz. As 50 feet : 46 : : 6 knots : 5.52 knots. Then, As 35 seconds : 30 seconds : : 5.52 knots : 4.73 knots. Consequently the true rate of sailing is 4.73 miles an hour.

Case II. If the glass is less than 30 seconds, and the space between knot and knot is more than 50 feet; then the distance given by the log will always be less than the true distance, since either of these errors lessens that true distance.

Example. Suppose a ship is found to run at the rate of 7 knots; but examining the glass, I find it runs only 25 seconds; and measuring the space between knot and knot on the log-line, I find it is 54 feet: required the true rate of sailing.

First, As 25 seconds : 30 seconds : : 7 knots : 8 knots. Then, As 50 feet : 54 feet : : 8, 4 knots: 9.072 knots. Consequently the true rate of sailing is 9.072 miles an hour.

Case III. If the glass runs more than 30 seconds, and the space between knot and knot is greater than 50 feet; or if the glass runs less than 30 seconds, and the space between knot and knot is greater than 50 feet: then, since in either of these two cases the effects of the errors are contrary, it is plain the distance will sometimes be too great, and sometimes too little, according as the greater quantity of the error lies; as will be evident from the following examples:

Example I. Suppose a ship is found to run at the rate of $9\frac{1}{2}$ knots per glass; but examining the glass, it is found to run 36 seconds; and by measuring the space between knot and knot, it is found to be 58 feet; required the true rate of sailing.

First, As 50 feet : 58 feet : : 9.5 knots : 11.20 knots. Then, As 38 seconds : 30 seconds : : 11.02 knots : 8.7 knots. Consequently the ship's true rate of sailing is 8.7 miles an hour.

Example II. Suppose a ship runs at the rate of 6 knots per glass; but examining the glass, it is found to run only 20 seconds; and by measuring the log-line, the distance between knot and knot is found to be but 38 feet: required the true rate of sailing.

First, As 50 feet : 38 feet : : 6 knots : 4.56 knots. Then, As 20 seconds : 30 seconds : : 4.56 knots : 6.84 knots. Consequently the true rate of sailing is 6.83 miles an hour.

But if in this case it happens, that the time the glass takes to run, is to the distance between knot and knot, as 30, the seconds in half a minute, is to 50, the true distance between knot and knot; then it is plain, that whatever number of seconds the glass consists of, and whatever number of feet is contained between knot and knot, yet the distance given by the log-line will be the true distance in miles.

The meridian and prime vertical of any place cuts the horizon in four points, at 90 degrees distance from one another, viz. North South, East, and West: that part of the meridian which extends itself from the place to the north point of the horizon is called the north line; that which tends to the south point of the horizon is called the south line; and that part of the prime vertical which extends towards the right hand of the observer when his face is turned to the north, is called the east-line; and lastly, that part of the prime vertical which tends towards the left hand is called the west line; the four points in which these lines meet the horizon are called the cardinal points.

In order to determine the course of the wind and to discover the various alterations or shiftings, each quadrant of the horizon, intercepted between the meridian and prime vertical, is usually divided into eight equal parts, and consequently the whole horizon into thirty-two; and the lines drawn from the place on which the observer stands, to the points of division in his horizon, are called rhumb-lines; the four principal of which are those described in the preceding paragraph, each of them having its name from the cardinal point in the horizon towards which it tends: the rest of the rhumb-lines have their names compounded of the principal lines on each side of them, as in the figure; and over whichsoever of these lines the course of the wind is directed, that wind takes its name accordingly. See MAGNETISM.

Hence it follows, that all rhumbs, except the four cardinals, must be curves or hemispherical lines, always tending towards the pole, and approaching it by infinite gyrations or turnings, but never falling into it. Thus let P, Plate Miscel. fig. 172, be the pole, EQ an arch of the equator, PE, PA, &c. meridians, and EFGHKL any rhumb: then because the angles PEF, PFG, &c. are by the nature of the rhumb-line equal, it is evident that it will form a curve-line on the surface of the globe always approaching the pole P, but never falling into it; for if it were possible for it to fall into the pole, then it would follow, that the same line could cut an infinite number of other lines at equal angles, in the same point; which is absurd.

Because there are 32 rhumbs or points in the compass equally distant from one another, therefore the angle contained between any two of them adjacent will be 11° 15′, viz. $\frac{1}{32}$ part of 360°; and so the angle contained between the meridian and the N*b*E will be 11° 15′, and between the meridian and the NNE will 22° 30′; and so of the rest. See Table of the angles &c. at the beginning of the article.

Concerning currents, and how to make proper allowances. 1. Currents are certain settings of the stream, by which all bodies (as ships, &c.) moving therein, are compelled to alter their course or velocity, or both; and submit to the motion impressed upon them by the current.

Case I. If the current sets just the course of the ship, *i. e.* moves on the same rhumb with it; then the motion of the ship is increased, by as much as is the drift or velocity of the current.

Example. Suppose a ship sails SE*b*S at the rate of 6 miles an hour, in a current that sets SE*b*S 2 miles an hour: required her true true rate of sailing.

Here it is evident that the ship's true rate of sailing will be 8 miles an hour.

Case II. If the current sets directly against the ship's course, then the motion of the ship is lessened by as much as is the velocity of the current.

Example. Suppose a ship sails SSW at the rate of 10 miles an hour, in a current that sets NNE 6 miles an hour, required the ship's true rate of sailing.

Here it is evident, that the ship's true rate of sailing will be 4 miles an hour. Hence it is plain,

1. If the velocity of the current is less than the velocity of the ship, then the ship will get so much ahead as is the difference of these velocities.

2. If the velocity of the current is greater than that of the ship, then the ship will fall so much astern as is the difference of these velocities.

3. Lastly, if the velocity of the current is equal to that of the ship, then the ship will stand still, the one velocity destroying the other.

Case III. If the current thwarts the course of the ship, then it not only lessens or augments her velocity, but gives her a new direction, compounded of the course she steers and the setting of the current.

The method of keeping a journal at sea, and how to correct it; by making proper allowance for the lee-way, variation, &c. 1. Lee-way is the angle that the rhumb-line, upon which the ship endeavours to sail, makes with the rhumb she really sails upon. This is occasioned by the force of the wind or surge of the sea, when she lies to the windward, or is close hauled, which causes her to fall off and glide sideways from the point of the compass she capes at. Thus let NESW (fig. 22,) represent the compass; and suppose a ship at C capes at, or endeavours to sail upon, the rhumb C*a*; but by the force of the wind, and surge of the sea, she is obliged to fall off, and make her way good upon the rhumb C*b*; then the angle *a*C*b* is the lee-way; and if that angle is equal to one point, the ship is said to make one point lee-way; and if equal to two points, the ship is said to make two points lee-way, &c.

2. The quantity of this angle is very uncertain, because some ships, with the same quantity of sail, and with the same gale, will make more lee-way than others; it depending much upon the mould and trim of the ship, and the quantity of water that she draws. The common allowances that are generally made for the lee-way, are as follow:

(1.) If a ship is close hauled, has all her sails set, the water smooth, and a moderate gale of wind, she is then supposed to make little or no lee-way. (2.) If it blows so fresh as to cause the small sails to be handed, it is usual to allow one point. (3.) If it blows so hard that the top-sails must be close-reefed, then the common allowance is two points for lee-way. (4.) If one top-sail must be handed, then the ship is supposed to make between two and three points lee-way. (5.) When both top-sails must be handed, then the allowance is about four points for lee-way. (6.) If it blows so hard as to occasion the fore-course to be handed, the allowance is between $5\frac{1}{2}$ and 6 points. (7.) When both main and fore-courses must be handed, then 6 or $6\frac{1}{2}$ points are commonly allowed for lee-way. (8.) When the mizen is handed, and the ship is trying ahull, she is then commonly allowed about 7 points for lee-way.

3. Though these rules are such as are generally made use of, yet since the lee-way depends much upon the mould and trim of the ship, it is evident that they cannot exactly serve to every ship; and therefore the best way is to find it by observation. Thus, let the ship's wake be set by a compass in the poop, and the opposite rhumb is the true course made good by the ship; then the difference between this and the course given by the compass in the binacle, is the lee-way required. If the ship is within sight of land, then the lee-way may be exactly found by observing a point on the land which continues to bear the same way; and the distance between the point of the compass it lies upon, and the point the ship capes at, will be the lee-way. Thus, suppose a ship at C is lying up N*b*W (fig. 23) towards A; but instead of keeping that course, she is carried on the NNE line CB, and consequently the point B continues to bear the same way from the ship; here it is evident that the angle ACB (or the distance between the N*b*W line that the ship capes at, and the NNE line that the ship really sails upon) will be the lee-way.

4. Having the course steered and the lee-way given, we may from thence find the true course by the following method, viz. Let your face be turned directly to the windward; and if the ship has her larboard tacks on board, count the lee-way from the course steered towards the right hand; but if the starboard tacks are on board, then count it from the course steered towards the left hand. Thus, suppose the wind at north, and the ship lies up within six points of the wind, with her larboard tacks on board, making one point lee-way; here it is plain that the course steered is ENE, and the true course E*b*N: also suppose the wind is at NNW, and the ship lies up within $6\frac{1}{2}$ points of the wind, with her starboard tack on board, making $1\frac{1}{2}$ point lee-way; it is evident that the true course, in this case, is WSW.

5. We have this general rule for finding the ship's true course, having the course steered and the variation given, viz. Let your face be turned towards the point of the compass upon which the ship is steered; and if the variation is easterly, count the quantity of it from the course steered towards the right hand, but if westerly towards the left hand; and the course thus found is the true course steered. Thus, suppose the course steered is N*b*E, and the variation one point easterly, then the true course steered will be NNE; also suppose the course steered is NE*b*E, and the variation one point westerly, then in this case the true course will be NE: and so of others.

Hence, by knowing the lee-way, variation, and course steered, we may from thence find the ship's true course; but if there is a current under foot, then that must be tried, and proper allowances made for it, as has been shown in the section concerning currents, from thence to find the true course.

6. After making all the proper allowances for finding the ship's true course, and making as just an estimate of the distance as we can; yet by reason of the many accidents that attend a ship in a day's running, such as different rates of sailing between the times of heaving the log, the want of due care at the helm by not keeping her steady but suffering her to yaw and fall off, sudden storms when no account can be kept, &c. the latitude by account frequently differs from the latitude by observation; and when that happens, it is evident there must be some error in the reckoning: to discover which, and where it lies, and also how to correct the reckoning, you may observe the following rules:

1st. If the ship sails near the meridian, or within 2 or $2\frac{1}{2}$ points thereof, then if the latitude by account disagrees with the latitude by observation, it is most likely that the error lies in the distance run; for it is plain, that in this case it will require a very sensible error in the course to make any considerable error in the difference of latitude, which cannot well happen if due care is taken at the helm, and proper allowances are made for the lee-way, variation, and currents. Consequently, if the course is pretty near the truth, and the error in the distance runs regularly through the whole, we may, from the latitude obtained by observation, correct the distance and departure by account, by the following analogies, viz.

As the difference of latitude by account
is to the true difference of latitude,
So is the departure by account
to the true departure,
And so is the direct distance by account
to the true direct distance.

The reason of this is plain; for let AB, fig. 24, denote the meridian of the ship at A; and suppose the ship sails upon the rhumb AE near the meridian, till by account she is found in C, and consequently her difference of latitude by account is AB; but by observation she is found in the parallel ED, and so her true difference of latitude is AD, her true distance AE, and her true departure DE; then, since the triangles ABC, ADE, are similar, it will be AB : AD :: BC : DE, and AB : AD :: AC : AE.

Example. Suppose a ship from the latitude of 45° 20′ north, after having sailed upon several courses near the meridian for 24 hours, her difference of latitude is computed to be upon the whole 95 miles southerly, and her departure 34 miles easterly; but by observation she is found to be in the latitude of 43° 10′ north, and consequently her true difference of latitude is 130 miles southerly; then for the true departure, it will be, As the difference of latitude by account 95, is to the true difference of latitude 130, so is the departure by account 34, to the true departure 46.52, and so is the distance by account 100.9, to the true distance 138.

2dly, If the courses are for the most part near the parallel of east and west, and the direct course is within $5\frac{1}{2}$ or 6 points of the meridian; then if the latitude by account differs from the observed latitude, it is most probable that the error lies in the course or distance, or perhaps both; for in this case it is evident, the departure by account will be very nearly true; and thence by the help of this, and the true difference of latitude, may the true course and direct distance be readily found by case 4. of plane sailing.

The form of the log-book and journal, together with an example of a day's work, are here subjoined.

To express the days of the week, we commonly use the characters by which the sun and planets are expressed, viz. ☉ denotes Sunday, ☽ Monday, ♂ Tuesday, ☿ Wednesday, ♃ Thursday, ♀ Friday, ♄ Saturday.

Hence the ship, by account, has come to the latitude of 47° 46′ north, and has differed her longitude 2° 5′ westerly; so this day I have made my way good S. 31° 31′ W. distance 157.4 miles.

At noon the Lizard bore from me N. 31° 31′ E. distance 157.4 miles; and having observed the latitude, I found it agreed with the latitude by account.

We have under the article LONGITUDE shewn the method of finding the longitude at sea by means of timekeepers. For the method of doing the same by lunar observations, we refer to the Nautical Almanac, and the tables that accompany it.

NAUTILUS, in zoology, a genus belonging to the order of vermes testaceæ. The shell consists of one spiral valve, divided into several apartments by partitions. There are 17 species, chiefly distinguished by particularities in their shells.

The most remarkable division of the nautili is into the thin and thick-shelled kinds. The first is called nautilus papyraceus; and its shell is indeed no thicker than a piece of paper when out of the water. This species is not at all fastened to its shell; but there is an opinion, as old as the days of Pliny, that this creature creeps out of its shell, and goes on shore to feed. When this species is to sail, it expands two of its arms on high, and between these supports a membrane which it throws out on this occasion; this serves for its sail: and the two other arms it hangs out of its shell, to serve occasionally either as oars or as a steerage; but this last office is generally served by the tail. When the sea is calm, it is common to see numbers of these creatures diverting themselves in this manner; but as soon as a storm rises, or any thing gives them disturbance, they draw in their legs, and take in as much water as makes them specifically heavier than that in which they float; and they sink to the bottom. When they rise again, they void this water by a number of holes, of which their legs are full. The other nautilus, whose shell is thick, never quits that habitation. This shell is divided into 40 or more partitions, which grow smaller and smaller as they approach the extremity or centre of the shell; between every one of these cells and the adjoining ones, there is a communication by means of a hole in the centre of every one of the partitions. Through this hole there runs a pipe of the whole length of the shell. It is supposed by many, that by means of this pipe the fish occasionally passes from one cell to another; but this seems by no means probable, as the fish must undoubtedly be crushed to death by passing through it. It is much more likely that the fish always occupies the largest chamber in its shell; that is, that it lives in the cavity between the mouth and the first partition, and that it never removes out of this; but that all the apparatus of cells and a pipe of communication, which we so much admire, serves only to admit occasionally air or water into the shell, in such proportion as may serve the creature in its intentions of swimming.

Some authors call this shell the concha margaritifera; but this can be only on account of the fine colour on its inside, which is more beautiful than any other mother-of-pearl; for it has not been observed that this species of fish ever produced pearls. It must be observed, that the polypus is by no means to be confounded with the paper-shelled nautilus, notwithstanding the great resemblance in the arms and body of the inclosed fish; nor is the cornu ammonis, so frequently found fossil, to be confounded with the thick-shelled nautilus, though the concamerations and general structure of the shell are alike in both; for there are great and essential differences between all these genera.

NAZARITES, among the Jews, persons who either of themselves, or by their parents, were dedicated to the observation of Nazariteship. They were of two sorts, namely, such as were bound to this observance for only a short time, as a week or month; and those who were bound to it all their lives. All that we find peculiar in the latter's way of life is, that they were to abstain from wine and all intoxicating liquors, and never to shave or cut off the hairs of their heads. The first sort of Nazarites were moreover to avoid all defilement; and if they chanced to contract any pollution before the term was expired, they were obliged to begin afresh. Women as well as men might bind themselves to this vow.

NE ADMITTAS, in law, a writ directed to the bishop, at the suit of one that is patron of a church, where, on a quare impedit, &c. depending, he is doubtful that the bishop will collate his clerk, or admit the other's clerk, during the suit between them.

NEAT, or NET-WEIGHT, the weight of a commodity alone, clear of the cask, bag, case, or even filth.

NEBULOUS, *cloudy*, in astronomy, a term applied to certain of the fixed stars, which shew a dim hazy light, being less than those of the sixth magnitude, and therefore scarce visible to the naked eye.

NECESSITY. The law charges no man with default where the act is compulsory, and not voluntary, and where there are not a consent and election; and therefore if either there is an impossibility for a man to do otherwise, or so great a perturbation of the judgment and reason as in presumption of law man's nature cannot overcome, such necessity carries a privilege in itself.

Necessity is of three sorts; necessity of conservation of life, necessity of obedience, and necessity of the act of God, or of a stranger.

And first, of conservation of life; if a man steals viands to satisfy his present hunger, this is no felony nor larceny.

The second necessity is of obedience; and therefore where baron and feme commit a felony, the feme can neither be principal nor accessary, because the law intends her to have no will in regard of the subjection and obedience she owes her husband.

The third necessity is of the act of God, or of a stranger; as if a man is particular tenant for years of a house, and it should be overthrown by thunder, lightning, and tempest, in this case, he is excused of waste. Bac. Elem. 25, 26, 27.

NECK. See ANATOMY.

NECKERIA, a genus of the class and order cryptogamia musci, but little known.

NECTARIUM. See BOTANY, vol. i. p. 254.

NECTRIS, a genus of the hexandria digynia class and order: the calyx is one-leafed, six-parted, coloured; corolla none; styles permanent; caps. two; superior ovate, one-celled, many-seeded; there is one species, a native of Guiana.

NECYDALIS, a genus of insects belonging to the order of coleoptera. The feelers are setaceous; the elytra are shorter and narrower than the wings; the tail is simple. There are 11 species, chiefly distinguished by the size and figure of the elytra.

NEEDLE, a very common small instrument or utensil, made of steel, pointed at one end, and pierced at the other, used in sewing, embroidery, tapestry, &c. Needles make a very considerable article in commerce, though there is scarcely any commodity cheaper, the consumption of them being almost incredible. The sizes are from N° 1. the largest, to N° 25. the smallest. In the manufacture of needles, German and Hungarian steel are of most repute. In the making of them, the first thing is to pass the steel through a coal-fire, and under a hammer, to bring it out of its square figure into a cylindrical one. This done, it is drawn through a large hole of a wiredrawing-iron, and returned into the fire, and drawn through a second hole of the iron, smaller than the first, and thus successively, from hole to hole, till it has acquired the degree of fineness required for that species of needles, observing every time it is to be drawn that it is greased over with lard, to render it more manageable. The steel thus reduced to a fine wire, is cut in pieces of the length of the needles intended. These pieces are flatted at one end on the anvil, in order to form the head and eye; they are then put into the fire to soften them farther, and thence taken out and pierced at each extreme of the flat part on the anvil, by force of a puncheon of well-tempered steel; and laid on a leaden block to bring out, with another puncheon, the little piece of steel remaining in the eye. The corners are then filed off the square of the heads, and a little cavity filed on each side of the flat of the head; this done, the point is formed with a file, and the whole filed over; they are then laid to heat red-hot on a long flat narrow iron, crooked at one end, in a charcoal-fire, and when taken out, are thrown into a bason of cold water to harden. On this operation a good deal depends; too much heat burns them, and too little leaves them soft: the medium is learned by experience. When they are thus hardened, they are laid in an iron shovel on a fire, more or less brisk in proportion to the thickness of the needles; taking care to move them from time to time. This serves to temper them, and take off their brittleness: great care here too must be taken of the degree of heat. They are then straightened one after another with the hammer, the coldness of the water used in hardening them having twisted the greatest part of them. The next process is the polishing them. To do this they take twelve or fifteen thousand needles, and range them in little heaps against each other in a piece of new buckram sprinkled with emery-dust. The needles thus disposed, emery dust is thrown over them, which is again sprinkled with oil of olives: at last the whole is made up into a roll, well bound at both ends. This roll is then laid on a polishing-table; and over it a thick plank loaden with stones, which two men work backwards and forwards a day and a half, or two days, successively; by which means the roll being continually agitated by the weight and motion of the plank over it, the needles withinside being rubbed against each other with oil and emery, are insensibly polished. After polishing they are taken out, and the filth washed off them with hot water and soap; they are then wiped in hot bran, a little moistened, placed with the needles in a round box, and suspended in the air by a cord, which is kept stirring till the bran and needles are dry. The needles thus wiped in two or three different brans are taken out and put in wooden vessels, to have the good separated from those whose points or eyes have been broken, either in polishing or wiping; the points are then all turned the same way, and smoothed with an emery-stone turned with a wheel. This operation finishes them, and there remains nothing but to make them into packets of two hundred and fifty each.

NE EXEAT REGNO, is a writ to restrain a person from going out of the kingdom without the king's licence.

Within the realm, the king may command the attendance and service of all his liegemen; but he cannot send any man out of the realm, or even upon the public service, except seamen and soldiers, the nature of whose employment necessarily implies an exception. 1 Black. 138.

This writ is now mostly used where a suit is commenced in the court of chancery against a man, and he intending to defeat the other of his just demand, or to avoid the justice and equity of the court, is about to go beyond sea, or however, that the duty will be endangered if he goes.

If the writ is granted on behalf of a subject, and the party is taken, he either gives security by bond in such sum as is demanded, or he satisfies the court by answering (where the answer is not already in) or by affidavit, that he intends not to go out of the realm, and gives such reasonable security as the court directs, and then he is discharged. P. R. C. 252.

NEGLIGENCE, is where a person neglects or omits to do a thing which he is obliged by law to do. Thus where one has goods of another to keep till such a time, and he has a certain recompence or reward for the keeping, he shall stand charged for injury by negligence, &c.

NEPA, a genus of insects of the order hemeptera; the generic character is, snout inflected; wings four, cross-complicate, coriaceous on the upper part; fore-feet cheliform, the rest formed for walking. This genus is aquatic, inhabiting stagnant waters, and preying on the smaller water-insects, &c. The largest species yet known, and which very far surpasses in size all the European animals of the genus, is the nepa grandis, which is a native of Surinam and other parts of South America, often measuring more than three inches in length. Its colour is a dull yellowish-brown, with a few darker shades or variegations; the under wings are of a semitransparent white colour, and the abdomen is terminated by a short tubular process.

Nepa cinerea, or the common water-scorpion, is a very frequent inhabitant of stagnant waters in our own country, measuring about an inch in length, and appearing, when the wings are closed, entirely of a dull brown colour; but when the wings are expanded, the body appears of a bright red colour above, with a black longitudinal band down the middle; and the lower wings, which are of a fine transparent white, are decorated with red veins: from the tail proceeds a tubular bifid process or style, nearly of the length of the body, and which appears single on a general view, the two valves of which it consists being generally applied close to each other throughout their whole length. The animal is of slow motion, and is often found creeping about the shallow parts of ponds, &c. In the month of May it deposits its eggs on the soft surface of the mud at the bottom of the water; they are of a singular shape, resembling some of the crowned seeds, having an oval body, and an upper part surrounded by seven radiating processes or curved spines; the young, when first hatched, are not more than the eighth of an inch in length. The water-scorpion flies only by night, when it wanders about the fields in the neighbourhood of its native waters. The larvæ and pupæ differ in appearance from the complete insect, in having only the rudiments of wings, and being of a paler or yellower colour. See Plate Nat. Hist. fig. 292.

Nepa cimicoides of Linnæus differs materially from the preceding species, and has at first view more the aspect of a notonecta than a nepa, the hind legs being formed for swimming briskly, and furnished with an edging of hairs on the inner side. This insect is less common than the preceding, but is found in similar situations.

Nepa linearis is an insect of a highly singular aspect, bearing a distant resemblance to some of the smaller insects of the genera mantis and phasma. It measures about an inch and a half from the tip of the snout to the beginning of the abdominal style or process, which is itself of equal length to the former part, and the whole animal is extremely slender in proportion to its length; the legs also are long and slender, and the chelæ or fore-legs much longer in proportion than those of the second species or nepa cinerea; the colour of the animal is dull yellowish-brown; the back, when the wings are expanded, appearing of a brownish-red, and the under wings white and transparent. It inhabits the larger kind of stagnant waters, frequenting the shallower parts during the middle of the day, when it may be observed to prey on the smaller water-insects, &c. Its motions are singular, often striking out all its legs in a kind of starting manner at intervals, and continuing this exercise for a considerable time. The eggs are smaller than those of the nepa cinerea, of an oval shape, and furnished with two processes or bristles divaricating from the top of each. See Plate Nat. Hist. fig. 293.

There are 14 species.

NEPENTHES, a genus of the tetrandria order, in the gynandria class of plants, and in the natural method ranking among those of which the order is doubtful. The calyx is quadripartite; there is no corolla; the capsule is quadrilocular. There is one species, a plant of Ceylon.

NEPER's RODS, or Bones, an instrument invented by J. Neper, baron of Merchiston, in Scotland, whereby the multiplication and division of large numbers are much facilitated.

Neper's rod, *the construction of.* Suppose the common table of multiplication to be made upon a plate of metal, ivory, or pasteboard, and then conceive the several columns (standing downwards from the digits on the head) to be cut asunder; and these are what we call Neper's rods for multiplication. But then there must be a good number of each; for as many times as any figure is in the multiplicand, so many rods of that species (*i. e.* with that figure on the top of it) must we have; though six rods of each species will be sufficient for any example in common affairs; there must be also as many rods of 0's.

But before we explain the way of using these rods, there is another thing to be known, viz. that the figures on every rod are written in an order different from that in the table. Thus, the little square space or division in which the several products of every column are written, is divided into two parts by a line across from the upper angle on the right to the lower on the left; and if the product is a digit, it is set in the lower division; if it has two places, the first is set in the lower, and the second in the upper division; but the spaces on the top are not divided. Also there is a rod of digits, not divided, which is called the index-rod; and of this we need but one single rod. See the figure of all the different rods, and the index, separate from one another, in plate Miscel. fig. 174.

Neper's rod, *multiplication by*. First lay down the index-rod; then on the right of it set the rod whose top is the figure in the highest place of the multiplicand; next to this again set the rod whose top is next the figure of the multiplicand; and so on in order to the first figure. Then is your multiplicand tabulated for all the nine digits; for in the same line of squares standing against every figure of the index-rod, you have the product of that figure, and therefore you have no more to do than to transfer the products and sum them. But in taking out these products from the rods, the order in which the figures stand obliges you to a very easy and small addition; thus, begin to take out the figure in the lower part, or unit's place, of the square of the first rod on the right; add the figure in the upper part of this rod to that in the lower part of the next, and so on, which may be done as fast as you can look on them. To make this practice as clear as possible, take the following example.

Example: To multiply 4768 by 385. Having set the rods together for the number 4768, against 5 in the index I find this number, by adding according to the rule - 23840
Against 8 this number - - 38144
Against 3 this number - - 14304
Total product 1835680

To make the use of the rods yet more regular and easy, they are kept in a flat square box, whose breadth is that of ten rods, and the length that of one rod, as thick as to hold six (or as many as you please); the capacity of the box being divided into ten cells, for the different species of rods. When the rods are put up in the box (each species in its own cell distinguished by the first figure of the rod set before it on the face of the box near the top), as much of every rod stands without the box as shews the first figure of that rod; also upon one of the flat sides without and near the edge, upon the left hand the index-rod is fixed; and along the foot there is a small ledge, so that the rods when applied are laid upon this side, and supported by the ledge, which makes the practice very easy; but in case the multiplicand should have more than 9 places, the upper face of the box may be made broader. Some make the rods with four different faces and figures on each for different purposes.

Neper's rods, *division by*. First tabulate your divisor; then you have it multiplied by all the digits, out of which you may choose such convenient divisors as will be next less to the figures in the dividend, and write the index answering in the quotient, and so continually till the work is done. Thus 2179788 divided by 6123, gives in the quotient 356.

Having tabulated the divisor, 6123, you see that 6123 cannot be had in 2179; therefore take five places, and on the rods find a number that is equal, or next less, to 21797, which is 18369; that is 3 times the divisor, wherefore set 3 in the quotient, and subtract 18369 from the figures above, and there will remain 3428; to which add 8, the next figure of the dividend, and seek again on the rods for it, or the next less, which you will find to be five times; therefore set 5 in the quotient, and subtract 30615 from 34288, and there will remain 3673; to which add 8, the last figure in the dividend, and finding it to be just 6 times the divisor, set 6 in the quotient.

NEPETA, Catmint, or Nep, a genus of the gymnospermia order, in the didynamia class of plants; and in the natural method ranking under the 42d order, verticillatæ. The under lip of the corolla has a small middle segment crenated; the margin of the throat is reflexed; the stamina approach one another. There are 20 species; the most remarkable is the cataria, common nep, or catmint. This is a native of many parts of Britain, growing about hedges and in waste places. The plant has a bitter taste, and strong smell, not unlike pennyroyal. An infusion of this plant is reckoned a good cephalic and emmenagogue; being found very efficacious in chlorotic cases. Two ounces of the expressed juice may be given for a dose. It is called catmint, because cats are very fond of it, especially when it is withered; for then they will roll themselves on it, and tear it to pieces, chewing it in their mouths with great pleasure.

NEPHELIUM, a genus of the pentandria order, in the monœcia class of plants. The male calyx is quinquedentate; there is no corolla: the female calyx is quadrifid; there is no corolla. There are two germens and two styles on each: the fruit are two dry plumbs, muricated, and monospermous. There is one species, a herb of the East Indies.

NEPHRITIC WOOD, lignum nephriticum, a wood of a very dense and compact texture, and of a fine grain, brought us from New Spain, in small blocks, in its natural state, and covered with its bark. It is to be chosen of a pale colour, sound and firm, and such as has not lost its acrid taste; but the surest test of it is the infusing it in water; for a piece of it infused only half an hour in cold water, gives it a changeable colour, which is blue or yellow, as variously held to the light. If the phial it is in is held between the eye and the light, the tincture appears yellow; but if the eye is placed between the light and the phial, it appears blue.

This wood is a very good diuretic, and is said to be of great use with the Indians in all diseases of the kidneys and bladder, and in suppressions of urine from whatever cause. It is also commended in fevers and obstructions of the viscera. The way of taking it, among the Indians, is only an infusion in cold water.

NEPHRITIS. See Medicine.

NEREIS, in zoology, a genus of animals belonging to the order of vermes mollusca. The body is oblong, linear, and fitted for creeping; it is furnished with lateral pencilled tentacula. There are 11 species, of which the most remarkable are the five following: 1. The noctiluca, or noctilucous nereis, which inhabits almost every sea, and is one of the causes of the luminousness of the water. These creatures shine like glow-worms, but with a brighter splendour, so as at night to make the element appear as if on fire all around. Their bodies are so minute as to elude examination by the naked eye.

It is sometimes called nereis phosphorans; and is thus described by Griseline. The head is roundish and flat, and the mouth acuminated. The two horns or feelers are short and subulated. The eyes are prominent, and placed on each side of the head. The body is composed of about twenty-three segments or joints, which are much less nearer the tail than at the head. These segments on both sides the animal all end in a short conical apex, out of which proceeds a little bundle of hairs; from under these bundles the feet grow in the form of small flexile subulated figments destitute of any thing like claws. It is scarcely two lines long, and is quite pellucid, and its colour is that of water, green. They are found upon all kinds of marine plants; but they often leave them, and are found upon the surface of the water: they are frequent at all seasons, but especially in summer before stormy weather, when they are more agitated and more luminous. Their numbers, and wonderful agility, added to their pellucid and shining quality, do not a little contribute to their illuminating the sea, for myriads of those animalculæ may be contained in the portion of a small cup of seawater. Innumerable quantities of them lodge in the cavities of the scales of fishes, and to them probably do the fishes owe their noctilucous qualitity.

2. Nereis lacustris, or bog nereis (fig. 2.) The body of the size of a hog's short bristle, transparent, articulated, and on either side at every articulation provided with a short setaceous foot; interiorly it seems to consist in a manner of oval-shaped articulations, and a back formed by two lines bent backwards. It inhabits marshes abounding in clay, where it remains under ground, pushing out its other extremity by reason of its continual motion. When taken out it twists itself up. Is frequent in Sweden.

3. Nereis cirrosa, or waving nereis. The body is red, lumbriciform, with sixty-five notches, furnished on both sides with two rows of bristles. At each side of the head ten filaments, at the sides of the mouth many, twice as long as the former. It dwells in Norway, on rocks at the bottom of the sea. It vomits a red liquor, with which it tinges the water. See Plate Nat. Hist. fig. 294.

4. Nereis cærulea, or blue nereis. It inhabits the ocean, where it destroys the serpulæ and teredines. fig. 295.

5. Nereis gigantæa, or giant nereis, is a peculiar species of those large worms that make their way into decayed piles driven down into the sea, which they bore through and feed upon, whence they are called sea-worms, or nereis. From head to tail they are beset on either side with small tufts terminating in three points, which are like the fine hair-pencils used by painters, and composed of shining bristles of various colours. The upper part of the body in this worm is all over covered with small hairs. The rings of which it is formed are closely pressed together, and yield to the touch. The three rows of small tufts we have been describing, serve this nereis instead of feet, which it uses to go forwards as fishes do their fins. Fig. 296.

NERITA, a genus of vermes testacea: the generic character is; animal a limax; shell univalve, spiral, gibbous, flattish at bottom; aperture semiorbicular or semilunar; pillar-lip transversely truncate, flattish. There are about 80 species of this genus.

NERIUM, a genus of the monogynia order, in the pentandria class of plants, and in the natural method ranking under the 30th order, contortæ. There are two erect follicles; the seeds plumy; the tube of the corolla terminated by a lacerated crown. There are nine species, all of them natives of the warmer climates; the most remarkable of which are, 1. The oleander, South Sea rose; this is a beautiful shrub, cultivated in gardens on account of its flowers, which are of a fine red, and in clusters, but of an indifferent smell; the whole plant is poisonous, and especially the bark of the roots. The double variety is beautiful, but it should be kept in a stove. 2. The antidysintericum, a native of Ceylon; the bark of which is an article of the materia medica, under the name of conessi. 3. The tinctorium, a new species, with beautiful blue flowers, discovered by Dr. Roxburgh at Madras. A decoction of the leaves, with an addition of lime-water, makes an indigo of fine quality. The whole plant in all the neriums is of a poisonous quality, in that respect resembling apocynum.

NERTERIA, a genus of the class and order tetrandria digynia: the corolla is funnel-shaped, four cleft; superior berry two-celled; seeds solitary. There is one species, an annual of New Zealand.

NERVES. See Anatomy.

NESTORIANS, a christian sect, the followers of Nestorius, bishop and patriarch of Constantinople; who, about the year 429, taught that there were two persons in Jesus Christ, the divine and the human, which are united, not hypostatically or substantially, but in a mystical manner: whence he concluded, that Mary was the mother of Christ, and not the mother of God. For this opinion Nestorius was condemned and deposed by the council of Ephesus; and the decree of this council was confirmed by the emperor Theodosius, who banished the bishop to a monastery.

NETTINGS, in a ship, a sort of grates made of small ropes, seized together with rope-yarn or twine, and fixed on the quarters and in the tops; they are sometimes stretched upon the ledges from the waste-trees to the roof-trees, from the top of the forecastle to the poop; and sometimes are laid in the waste of a ship to serve instead of gratings.

NETTLE. See Urtica.

Nettle, *dead*. See Lamium.

NEURADA, a genus of the decagynia order, in the decandria class of plants, and in the natural method ranking under the 13th order, succulentæ. The calyx is quinquepartite; there are five petals; the capsule inferior, decemlocular, decaspermous, and aculeated. There is only one species, the procumbens. The whole plant is white and woolly; and is a native of the warm climates, and found on dry parched grounds.

NEUTRAL SALTS, among chemists, a sort of salts neither acid nor alkaline, but partaking of the nature of both. See Acid, Alkali, Chemistry, &c.

NEUTRALIZATION. When two or more substances mutually destroy each other's properties, they are said to neutralize one another. Thus, in a proper combination of acid and alkaline substances, the acid and alkaline properties are destroyed.

NEWEL. See Architecture.

NEWT. See Lacerta.

NEWTONIAN PHILOSOPHY, the doctrine of the universe, or the properties, laws, affections, actions, forces, motions, &c. of bodies, both celestial and terrestrial, as delivered by Newton.

The chief parts of the Newtonian philosophy, as delivered by the author, except his Optical Discoveries, &c. are contained in his Principia, or Mathematical Principles of Natural Philosophy. He founds his system on the following definitions.

1. Quantity of matter is the measure of the same, arising from its density and bulk conjointly. Thus, air of a double density, in the same space, is double in quantity; in a double space, is quadruple in quantity; in a triple space, is sextuple in quantity, &c.

2. Quantity of motion is the measure of the same, arising from the velocity and quantity of matter conjunctly. This is evident, because the motion of the whole is the motion of all its parts; and therefore in a body double in quantity, with equal velocity, the motion is double, &c.

3. The vis insita, vis inertiæ, or innate force of matter, is a power of resisting, by which every body, as much as in it lies, endeavours to persevere in its present state, whether it is of rest, or moving uniformly forward in a right line. This definition is proved to be just, by experience, from observing the difficulty with which any body is moved out of its place, upwards or obliquely; or even downwards, when acted on by a body endeavouring to urge it quicker than the velocity given it by gravity, and any how to change its state of motion or rest. And therefore this force is the same, whether the body has gravity or not; and a cannon-ball, void of gravity, if it could be, being discharged horizontally, will go the same distance in that direction, in the same time, as if it were endued with gravity.

4. An impressed force is an action exerted upon a body, in order to change its state, whether of rest or motion. This force consists in the action only; and remains no longer in the body when the action is over. For a body maintains every new state it acquires, by its vis inertiæ only.

5. A centripetal force is that by which bodies are drawn, impelled, or any way tend, towards a point, as to a centre. This may be considered of three kinds, absolute, accelerative, and motive.

6. The absolute quantity of a centripetal force is a measure of the same, proportional to the efficacy of the cause that urges it to the centre.

7. The accelerative quantity of a centripetal force, is the measure of the same proportional to the velocity which it generates in a given time.

8. The motive quantity of a centripetal force, is a measure of the same, proportional to the motion which it generates in a given time. This is always known by the quantity of force equal and contrary to it, that is just sufficient to hinder the descent of the body.

After these definitions, follow certain scholia, treating of the nature and distinctions of time, space, place, and motion, absolute, relative, apparent, true, real, &c. After which, the author proposes to shew how we are to collect the true motions from their causes, effects, and apparent differences; and vice versâ, how, from the motions, either true or apparent, we may come to the knowledge of their causes and effects. In order to this, he lays down the following axioms or laws of motion.

1st law. Every body perseveres in its state of rest, or of uniform motion in a right line, unless it is compelled to change that state by forces impressed upon it. Thus, "projectiles persevere in their motions, so far as they are not retarded by the resistance of the air, or impelled downwards by the force of gravity. A top, whose parts, by their cohesion, are perpetually drawn aside from rectilinear motions, does not cease its rotation otherwise than as it is retarded by the air. The greater bodies of the planets and comets, meeting with less resistance in more free spaces, preserve their motions, both progressive and circular, for a much longer time."

2d law. The alteration of motion is always proportional to the motive force impressed, and is made in the direction of the right line in which that force is impressed. Thus, if any force generates a certain quantity of motion, a double force will generate a double quantity, whether that force is impressed all at once or in successive moments.

3d law. To every action there is always opposed an equal re-action; or the mutual actions of two bodies upon each other, are always equal, and directed to contrary parts. Thus, whatever draws or presses another, is as much drawn or pressed by that other. If you press a stone with your finger, the finger is also pressed by the stone, &c.

From this axiom, or law, Newton deduces the following corollaries:

1. A body by two forces conjoined will describe the diagonal of a parallelogram, in the same time that it would describe the sides by those forces apart.

2. Hence is explained the composition of any one direct force out of any two oblique ones, viz. by making the two oblique forces the sides of a parallelogram, and the diagonal the direct one.

3. The quantity of motion, which is collected by taking the sum of the motions directed towards the same parts, and the difference of those that are directed to contrary parts, suffers no change from the action of bodies among themselves; because the motion which one body loses is communicated to another.

4. The common centre of gravity of two or more bodies does not alter its state of motion or rest by the actions of the bodies among themselves; and therefore the common centre of gravity of all bodies, acting upon each other, (excluding external actions and impediments) is either at rest, or moves uniformly in a right line.

5. The motions of bodies included in a given space are the same among themselves, whether that space is at rest, or moves uniformly forward in a right line without any circular motion. The truth of this is evident from the experiment of a ship; where all motions are just the same, whether the ship is at rest, or proceeds uniformly forward in a straight line.

6. If bodies, any how moved among themselves, are urged in the direction of parallel lines by equal accelerative forces, they will all continue to move among themselves, after the same manner as if they had not been urged by such forces.

The mathematical part of the Newtonian Philosophy depends chiefly on the following lemmas, especially the first, containing the doctrine of prime and ultimate ratios.

Lem. 1. Quantities, and the ratios of quantities, which in any finite time converge continually to equality, and before the end of that time approach nearer the one to the other than by any given difference, become ultimately equal.

Lem. 2. shews, that in a space bounded by two right lines and a curve, if an infinite number of parallelograms are inscribed, all of equal breadth; then the ultimate ratio of the curve space, and the sum of the parallelograms, will be a ratio of equality.

Lem. 3. shews, that the same thing is true when the breadths of the parallelograms are unequal.

In the succeeding lemmas it is shewn, in like manner, that the ultimate ratios of the sine, chord, and tangent, of arcs infinitely diminished, are ratios of equality; and therefore that in all our reasonings about these, we may safely use the one for the other: that the ultimate form of evanscent triangles, made by the arc, chord, or tangent, is that of similitude, and their ultimate ratio is that of equality; and hence, in reasonings about ultimate ratios, these triangles may safely be used one for another, whether they are made with the sine, the arc, or the tangent. He then demonstrates some properties of the ordinates of curvilinear figures; and shews that the spaces which a body describes by any finite force urging it, whether that force is determined and immutable, or continually varied, are to each other, in the very beginning of the motion, in the duplicate ratio of the forces; and lastly, having added some demonstrations concerning the evanescence of angles of contact, he proceeds to lay down the mathematical part of his system, which depends on the following theorems.

Theor. 1. The areas which revolving bodies describe by radii drawn to an immoveable centre of force, lie in the same immoveable planes, and are proportional to the times in which they are described. To this proposition are annexed several corollaries, respecting the velocities of bodies revolving by centripetal forces, the directions and proportions of those forces, &c. such as, that the velocity of such a revolving body is reciprocally as the perpendicular let fall from the centre of force upon the line touching the orbit in the place of the body, &c.

Theor. 2. Every body that moves in any curve line described in a plane, and by a radius drawn to a point either immoveable or moving forward with an uniform rectilinear motion, describes about that point areas proportional to the times, is urged by a centripetal force directed to that point. With corollaries relating to such motions in resisting mediums, and to the direction of the forces when the areas are not proportional to the times.

Theor. 3. Every body that, by a radius drawn to the centre of another body, any how moved, describes areas about that centre proportional to the times, is urged by a force compounded of the centripetal forces tending to that other body, and of the whole accelerative force by which that other body is impelled. With several corollaries.

Theor. 4. The centripetal forces of bodies which by equal motions describe different circles, tend to the centres of the same circles; and are one to the other as the squares of the arcs described in equal times, applied to the radii of the circles. With many corollaries relating to the velocities, times, periodic forces, &c. And, in a scholium, the author farther adds, moreover, by means of the foregoing proposition and its corollaries, we may discover the proportion of a centripetal force to any other known force, such as that of gravity. For if a body, by means of its gravity, revolves in a circle concentric to the earth, this gravity is the centripetal force of that body. But from the descent of heavy bodies, the time of one entire revolution, as well as the arc described in any given time, is given by a corollary to this proposition.

On these and such-like principles depends the Newtonian mathematical philosophy. The author farther shews how to find the centre to which the forces impelling any body are directed, having the velocity of the body given; and finds that the centrifugal force is always as the versed sine of the nascent arc directly, and as the square of the time inversely; or directly as the square of the velocity, and inversely as the chord of the nascent arc. From these premises, he deduces the method of finding the centripetal force directed to any given point when the body revolves in a circle; and this, whether the central point is near hand, or at immense distance; so that all the lines drawn from it may be taken for parallels. And he shews the same thing with regard to bodies revolving in spirals, ellipses, hyperbolas, or parabolas. He shews also, having the figures of the orbits given, how to find the velocities and moving powers; and indeed resolves the most difficult problems relating to the celestial bodies with a surprising degree of mathematical skill. These problems and demonstrations are all contained in the first book of the Principia; but an account of them here would neither be generally understood, nor easily comprised in the limits of this work.

In the second book, Newton treats of the properties and motion of fluids, and their powers of resistance, with the motion of bodies through such resisting mediums, those resistances being in the ratio of any powers of the velocities; and the motions being either made in right lines or curves, or vibrating like pendulums.

On entering upon the third book of the Principia, Newton briefly recapitulates the contents of the two former books in these words: " In the preceding books I have laid down the principles of philosophy, principles not philosophical, but mathematical; such, to wit, as we may build our reasonings upon in philosophical enquiries. These principles are, the laws and conditions of certain motions, and powers or forces, which chiefly have respect to philosophy. But lest they should have appeared of themselves dry and barren, I have illustrated them here and there with some philosophical scholiums, giving an account of such things as are of a more general nature, and which philosophy seems chiefly to be founded on; such as the density and the resistance of bodies, spaces void of all matter, and the motion of light and sounds. It remains, he adds, that from the same principles I now demonstrate the frame of the system of the world. Upon this subject I had indeed composed the third book in a popular method, that it might be read by many. But afterwards considering that such as had not sufficiently entered into the principles could not easily discern the strength of the consequences, nor lay aside the prejudices to which they had been many years accustomed; therefore to prevent the disputes which might be raised upon such accounts, I chose to reduce the substance of that book into the form of propositions, in the mathematical way, which should be read by those only who had first made themselves masters of the principles established in the preceding books."

As a necessary preliminary to this third part, Newton lays down rules for reasoning in natural philosophy.

The phenomena first considered are, 1. That the satellites of Jupiter, by radii drawn to his centre, describe areas proportional to the times of description; and that their periodic times, the fixed stars being at rest, are in the sesquiplicate ratio of their distances from that centre. 2. The same thing is likewise observed of the phenomena of Saturn. 3. The five primary planets, Mercury, Venus, Mars, Jupiter, Saturn, with their several orbits, encompass the sun. 4. The fixed stars being supposed at rest, the periodic times of the said five primary planets, and of the earth, about the sun, are in the sesquiplicate proportion of their mean distances from the sun. 5. The primary planets, by radii drawn to the earth, describe areas no ways proportional to the times; but the areas which they describe by radii drawn to the sun are proportional to the times of description. 6. The moon, by a radius drawn to the centre of the earth, describes an area proportional to the time of description. All which phenomena are clearly evinced by astronomical observations. The mathematical demonstrations are next applied by Newton in the following propositions.

Prop. 1. The forces by which the satellites of Jupiter are continually drawn off from rectilinear motions, and retained in their proper orbits, tend to the centre of that planet, and are reciprocally as the squares of the distances of those satellites from that centre.

Prop. 2. The same thing is true of the primary planets, with respect to the sun's centre.

Prop. 3. The same thing is also true of the moon, in respect of the earth's centre.

Prop. 4. The moon gravitates towards the earth; and by the force of gravity is continually drawn off from a rectilinear motion, and retained in her orbit.

Prop. 5. The same thing is true of all the other planets, both primary and secondary, each with respect to the centre of its motion.

Prop. 6. All bodies gravitate towards every planet; and the weights of bodies towards any one and the same planet, at equal distances from its centre, are proportional to the quantities of matter they contain.

Prop. 7. There is a power of gravity tending to all bodies, proportional to the several quantities of matter which they contain.

Prop. 8. In two spheres mutually gravitating each towards the other, if the matter in places on all sides, round about and equidistant from the centres, is similar, the weight of either sphere towards the other, will be reciprocally as the square of the distance between their centres. Hence are compared together the weights of bodies towards different planets; hence also are discovered the quantities of matter in the several planets; and hence likewise are found the densities from those planets.

Prop. 9. The force of gravity, in parts downwards from the surface of the planets towards their centres, decreases nearly in the proportion of the distances from those centres.

These, and many other propositions and corollaries, are proved or illustrated by a great variety of experiments, in all the great points of physical astronomy. See GRAVITY, GRAVITATION, &c.

NICANDRA, a genus of the monogynia order in the decandria class of plants, and in the natural method ranking under the 13th order, contortæ. The calyx is monophyllous and quadripartite; the corolla is monopetalous, tubulated, and parted into ten laciniæ; the fruit is an oval berry, which is grooved longitudinally, and contains many small angular seeds. Of this there is only one species, the amara, a native of Guiana. The leaves and stalks are bitter, and used by the natives as an emetic and purge.

NICHE. See ARCHITECTURE.

NICKEL, in mineralogy. There is found in different parts of Germany a heavy mineral of a reddish-brown colour, not unlike copper. When exposed to the air, it gradually loses its lustre, becomes at first brownish, and is at last covered with green spots. It was at first taken for an ore of copper; but as none of that metal can be extracted from it, the German miners give it the name of kupfernickel, or false copper. Hierne, who may be considered as the father of the Swedish chemists, is the first person who mentions this mineral. He gives a description of it in a book published by him in 1694 on the art of detecting metals. It was generally considered by mineralogists as an ore of copper, till it was examined by the celebrated Cronstedt. He concluded from his experiments, which were published in the Stockholm Transactions for 1751 and 1754, that it contained a new metal, to which he gave the name of nickel.

This opinion was embraced by all the Swedes, and indeed by the greater number of chemical philosophers. Some, however, particularly Sage and Monnet, affirmed, that it contained no new metal, but merely a compound of various known metals, which could be separated from each other by the usual processes. These assertions induced Bergman to undertake a very laborious course of experiments, in order, if possible, to obtain nickel in a state of purity; for Cronstedt had not been able to separate a quantity of arsenic, cobalt, and iron, which adhered to it with much obstinacy. These experiments, which were published in 1775, fully confirmed the conclusions of Cronstedt.

Nickel, when perfectly pure, is of a fine white colour, resembling silver; and like that metal it leaves a white trace when rubbed upon the polished surface of a hard stone. It is rather softer than iron. Its specific gravity is 9. Its malleability, while cold, is rather greater than that of iron, but it cannot be heated without being oxidated, and in consequence rendered brittle. It is attracted by the magnet as strongly as iron. Like that metal, it may be converted into a magnet; and in that state points to the north when freely suspended, precisely as a common magnetic needle. It requires for fusion a temperature at least equal to 150° Wedgewood. It has not hitherto been crystallized.

When heated in an open vessel, it combines with oxygen, and assumes a green colour; and if the heat is continued, acquires a tinge of purple. The oxide of nickel, according to Klaproth, is composed of 77 parts of nickel and 23 of oxygen.

Nickel has not been combined with carbon nor hydrogen, but it combines readily with sulphur and phosphorus. Cronstedt found that sulphuret of nickel may be easily formed by fusion. The sulphuret which he obtained was yellow and hard, with small sparkling facets; but the nickel which he employed was impure.

Phosphuret of nickel may be formed either by fusing nickel along with phosphoric glass, or by dropping phosphorus into it while red-hot. It is of a white colour, and when broke, it exhibits the appearance of very slender prisms collected together. When heated, the phosphorus burns, and the metal is oxidated. It is composed of 83 parts of nickel and 17 of phosphorus. The nickel however on which this experiment was made, was not pure.

Nickel is not acted upon by azote, nor does it combine with muriatic acid.

The alloys of this metal are but very imperfectly known. With gold it forms a white and brittle alloy; with copper a white, hard, brittle alloy, easily oxidized when exposed to the air; with iron it combines very readily, and forms an alloy whose properties have not been sufficiently examined; with tin it forms a white, hard, brittle mass, which swells up when heated; with lead it does not combine without difficulty; with silver and mercury it refuses to unite; its combination with platinum has not been tried.

The affinities of nickel, and its oxides, are, according to Bergman, as follows:

NICKEL.	OXIDE OF NICKEL.
Iron,	Oxalic acid,
Cobalt,	Muriatic,
Arsenic,	Sulphuric,
Copper,	Tartaric,
Gold,	Nitric,
Tin,	Phosphoric,
Antimony,	Fluoric,
Platinum,	Saclactic,
Bismuth,	Succinic,
Lead,	Citric,
Silver,	Lactic,
Zinc,	Acetic,
Sulphur,	Arsenic,
Phosphorus.	Boracic,
	Prussic,
	Carbonic.

NICKEL, *ores of.* Hitherto nickel has been found in too small quantities to be applied to any use; of course there are no mines of nickel. It usually occurs in secondary mountains, and commonly accompanies cobalt. It has been found in different parts of Germany, in Sweden, Siberia, Spain, France, and Britain.

NICOLAITANS, in church history, christian heretics who assumed this name from Nicolas of Antioch; who, being a gentile by birth, first embraced judaism, and then christianity; when his zeal and devotion recommended him to the church of Jerusalem, by whom he was chosen one of the first deacons.

NICOTIANA, *tobacco*, a genus of the monogynia order, in the pentandria class of plants, and in the natural method ranking under the 28th order, luridæ. The corolla is funnel-shaped, with a plaited limb; the stamina inclined; the capsule bivalved and bilocular. There are seven species, of which the most remarkable is the tabacum (see Plate Nat. Hist. fig. 297), or common tobacco-plant. This was first discovered in America by the Spaniards about the year 1560, and by them imported into Europe. It had been used by the inhabitants of America long before; and was called by those of the islands yoli, and pætun by the inhabitants of the continent. It was sent into Spain from Tabaco, a province of Yucatan, where it was first discovered, and whence it takes its common name.

There are two varieties of that species of nicotiana which is cultivated for common use; and which are distinguished by the names of Oronokoe, and sweet-scented tobacco. They differ from each other in the figure of their leaves; those of the former being longer and narrower than the latter. They are tall herbaceous plants, growing erect with fine foliage, and rising with a strong stem from six to nine feet high. The stalk, near the root, is upward of an inch diameter, and surrounded with a kind of hairy or velvet clammy substance, of a yellowish-green colour. The leaves are rather of a deeper green, and grow alternately at the distance of two or three inches from each other. They are oblong, of a spear-shaped oval, and simple; the largest about twenty inches long, but decreasing in size as they ascend, till they come to be only ten inches long, and about half as broad. The face of the leaves is much corrugated, like those of spinach when full-ripe. Before they come to maturity, when they are about five or six inches long, the leaves are generally of a full green, and rather smooth; but as they increase in size, they become rougher, and acquire a yellowish cast. The stem and branches are terminated by large bunches of flowers collected into clusters, of a delicate red; the edges, when full-blown, inclining to a pale purple. They continue in succession till the end of the summer; when they are succeeded by seeds of a brown colour, and kidney-shaped. These are very small, each capsule containing about 1000; and the whole produce of a single plant is reckoned at about 350,000. The seeds ripen in the month of September.

Mr. Carver informs us, that the Oronokoe, or, as it is called, the long Virginian tobacco, is the kind best suited for bearing the rigour of a northern climate; the strength, as well as the scent, of the leaves, being greater than that of the other. The sweet-scented sort flourishes most in a sandy soil, and in a warm climate, where it greatly exceeds the former in the celerity of its growth; and is likewise, as its name intimates, much more mild and pleasant.

Culture.—Tobacco thrives best in a warm, kindly, rich soil, that is not subject to be overrun by weeds. In Virginia the soil in which it thrives best is warm, light, and inclining to be sandy; and therefore if the plant is to be cultivated in Britain, it ought to be planted in a soil as nearly of the same kind as possible. Other kinds of soil might probably be brought to suit it, by a mixture of proper manure; but we must remember, that whatever manure is made use of must be thoroughly incorporated with the soil. The best situation for a tobacco-plantation is the southern declivity of a hill rather gradual than abrupt, or a spot that is sheltered from the north winds: but at the same time it is necessary that the plants enjoy a free air; for without that they will not prosper.

Having sown the seed, on the least apprehension of a frost after the plants appear, it will be necessary to spread mats over the beds, a little elevated from the ground by poles laid across, that they may not be crushed. When the tobacco has risen to the height of more than two feet, it commonly begins to put forth the branches on which the flowers and seeds are produced; but as this expansion, if suffered to take place, would drain the nutriment from the leaves, which are the most valuable part, and thereby lessen their size and efficacy, it becomes needful at this stage to nip off the extremity of the stalk to prevent its growing higher. In some climates the top is commonly cut off when the plant has 15 leaves: but if the tobacco is intended to be a little stronger than usual, this is done when it has only 13.

The apparent signs of maturity are these: the leaves, as they approach a state of ripeness, become more corrugated or rough; and when fully ripe appear mottled, with yellowish spots on the raised parts; whilst the cavities retain their usual green colour.

Tobacco is subject to be destroyed by a worm; and without proper care to exterminate this enemy, a whole field of plants may soon be lost. This animal is of the horned species, and appears to be peculiar to the tobacco-plant; so that in many parts of America it is distinguished by the name of the tobacco-worm. In what manner it is first produced, or how propagated, is unknown: but it is not discernible till the plants have attained about half their height; and then appears to be nearly as large as a gnat. Soon after this it lengthens into a worm; and by degrees increases in magnitude to the bigness of a man's finger. In shape it is regular from its head to its tail, without any diminution at either extremity. The colour of its skin is, in general, green, interspersed with several spots of a yellowish white; and the whole covered with a short hair scarcely to be discerned. These worms are found the most predominant during the end of July and the beginning of August; at which time the plants must be particularly attended to, and every leaf carefully searched. As soon as a wound is discovered (and it will not be long before it is perceptible), care must be taken to destroy the cause of it, which will be found near it, and from its unsubstantial texture may easily be crushed.

When the tobacco is fit for being gathered, on the first morning that promises a fair day, before the sun is risen, take an axe or a long knife, and holding the stalk near the top with one hand, sever it from its root with the other, as low as possible. Lay it gently on the ground, taking care not to break off the leaves, and there let it remain exposed to the rays of the sun throughout the day, or until the leaves, according to the American expression, are entirely wilted; that is, till they become limber, and will bend any way without breaking. But if the weather should prove rainy without any intervals of sunshine, and the plants appear to be fully ripe, they must be housed immediately. This must be done, however, with great care that the leaves, which are in this state very brittle, may not be broken. They are next to be placed under proper shelter, either in a barn or covered hovel, where they cannot be affected by rain or too much air, thinly scattered on the floor; and if the sun does not appear for several days, they must be left to wilt in that manner; but in this case the quality of the tobacco will not be quite so good.

When the leaves have acquired the abovementioned flexibility, the plants must be laid in heaps, or rather in one heap if the quantity is not too great, and in about 24 hours they will be found to sweat. But during this time, when they have lain for a little while, and begin to ferment, it will be necessary to turn them; bringing those which are in the middle to the surface, and placing those which are at the surface in the middle. The longer they lie in this situation, the darker-coloured is the tobacco. After they have lain for three or four days, for a longer continuance might make the plants turn mouldy, they may be fastened together in pairs with cords or wooden pegs, near the bottom of the stalk, and hung across a pole, with the leaves suspended in the same covered place, a proper interval being left between each pair. In about a month the leaves will be thoroughly dried, and of a proper temperature to be taken down. This state may be ascertained by their appearing of the same colour with those imported from America. But this can be done only in wet weather. The tobacco is exceedingly apt to attract the humidity of the atmosphere, which gives it a pliability that is absolutely necessary for its preservation; for if the plants are removed in a very dry season, the external parts of the leaves will crumble into dust, and a considerable waste will ensue.

Cure.—As soon as the plants are taken down, they must again be laid in a heap, and pressed with heavy logs of wood for about a week; but this climate may possibly require a longer time. While they remain in this state it will be necessary to introduce your hand frequently into the heap, to discover whether the heat is not too intense; for in large quantities this will sometimes be the case, and considerable damage will be occasioned by it. When they are found to heat too much, that is, when the heat exceeds a moderate glowing warmth, part of the weight by which they are pressed must be taken away; and the cause being removed, the effect will cease. This is called the second, or last sweating; and, when completed, which it generally will be about the time just mentioned, the leaves may be stripped from the stalks for use. Many, however, omit this last sweating.

When the leaves are stripped from the stalks, they are to be tied up in bunches or hands, and kept in a cellar or other damp place; though if not handled in dry weather, but only during a rainy season, it is of little consequence in what part of the house or barn they are laid up. At this period the tobacco is thoroughly cured, and as proper for manufacturing as that imported from the colonies.

Tobacco is made up into rolls by the inhabitants of the interior parts of America, by means of a machine called a tobacco-wheel. With this machine they spin the leaves after they are cured, into a twist of any size they think fit; and having folded it into rolls of about 20 pounds each, they lay it by for use. In this state it will keep for several years, and be continually improving, as it always grows milder. The Illinois usually form it into carrots; which is done by laying a number of leaves, when cured, on each other after the ribs have been taken out, and rolling them round with packthread till they become cemented together. These rolls commonly measure about 18 or 20 inches in length, and nine round in the middle part.

NICTITATING Membrane. See Comparative Anatomy.

NIGELLA, *fennel flower*, or *devil in a bush*, a genus of the pentagynia order, belonging to the pentandria class of plants. There is no calyx; the petals are five, and five trifid nectaria within the corolla; there are five connected capsules. There are five species, all of them annuals, and natives of the warm parts of Europe; and rising from a foot to a foot and a half high, adorned with blue or white flowers. They are propagated by seeds, which in a dry and warm situation will thrive very well; and the plants ripen seeds in this country.

NIGHT-MARE. See Medicine.

NIGRINA, in botany, a genus of the monogynia order, belonging to the pentandria class of plants. The corolla is funnel-shaped; the calyx inflated; the stigma obtuse; the capsule bilocular.

NIGRINE. This ore has hitherto been found only near Passau in Bavaria, and at Arendaal in Norway, and near St. Gothard. It was discovered by professor Hunger. It is sometimes disseminated, but more commonly crystallized, in four-sided prisms, not longer than one-fourth of an inch. Primitive form a rhomboidal prism.

Colour reddish, yellowish, or blackish-brown; sometimes whitish-grey. Powder whitish-grey. Lustre waxy, or nearly metallic. Texture foliated. Brittle. Specific gravity 3.510. Muriatic acid, by repeated digestion, dissolves one-third of it. Ammonia precipitates from this solution a clammy yellowish substance. Infusible by the blowpipe, and also in a clay crucible; but in charcoal is converted into a black, opaque, porous slag.

According to the analysis of Klaproth it is composed of

33	oxide of titanium
35	silica
33	lime
101.	

The mineral called sphene by Hauy belongs to this species. According to the analysis of Cordier it is composed of

33.3	oxide of titanium
28.0	silica
32.2	lime.
93.5	

NIHIL DICIT, a failure in the defendant to put in an answer to the plaintiff's declaration, &c. by the day assigned for that purpose, by which omission judgment of course is had against him.

NIMBUS, in antiquity, a circle observed on certain medals, or round the head of some emperors, answering to the circles of light drawn around the images of saints. The nimbus is seen on the medals of Maurice, Phocas, and others, even of the upper empire. See also METEOROLOGY.

NIPA, a genus of the natural order of palms. The male has a spathe; the corolla is six-petalled. The female has a spathe; corolla none; drupes angular.

There is one species, a native of the E. Indies. The leaves are used in making mats.

NIPPERS, in a ship, are small ropes about a fathom or two long, with a little truck at one end, and sometimes only a wale-knot. Their use is to help holding off the cable from the main or jeer-capstan, where the cable is so slimy, so wet, and so great, that they cannot strain it, to hold it off with their bare hands.

NISI PRIUS, in law, a commission directed to the judges of assize, empowering them to try all questions of fact issuing out of the courts at Westminster that are then ready for trial by jury. The original of which name is this: all causes commenced in the courts of Westminster-hall are, by course of the courts, appointed to be tried on a day fixed in some Easter or Michaelmas term, by a jury returned from the county wherein the cause of action arises; but with this proviso, nisi prius justiciarii ad assisas capiendas venerint: that is, unless before the day prefixed the judges of assize come into the county in question, which they always do in the vacation preceding each Easter and Michaelmas term, and there try the cause. And then, upon the return of the verdict given by the jury to the court above, the judges there give judgment for the party to whom the verdict is found. 3 Black. 59. See ASSIZES.

NISSOLIA, a genus of the decandria order, in the diadelphia class of plants, and in the natural method ranking under the 32d order, papilionaceæ. The calyx is quinquedentate; the capsule monospermous, and terminated by a ligulated wing. There are two species, trees of Carthagena.

NITIDULA, a genus of insects of the coleoptera order. The generic character is, antennæ clavate, the club solid; shells margined; head prominent; thorax a little flattened, margined. There are upwards of 30 species of this genus.

NITRARIA, a genus of the monogynia order, in the dodecandria class of plants, and in the natural method ranking with those of which the order is doubtful. The corolla is pentapetalous, with the petals arched at the top; the calyx quinquefid; the stamina 15; the fruit a monospermous plum. There is one species, a shrub of Siberia.

NITRATS, salts formed by the nitric acid. The most important of the nitrats have been long known; and in consequence of the singular properties which they possess, no class of bodies has excited greater attention, or been examined with more unwearied industry. See NITRE. They may be distinguished by the following properties:

1. Soluble in water, and capable of crystallizing by cooling. 2. When heated to redness, along with combustible bodies, a violent combustion and detonation are produced. 3. Sulphuric acid disengages from them fumes, which have the odour of nitric acid. 4. When heated along with muriatic acid, oxymuriatic acid is exhaled. 5. Decomposed by heat, and yield at first oxygen gas. The nitrats at present known are 12 in number. Few of them combine with an excess of acid or of base, so that there are hardly any supernitrats, or subnitrats.

NITRE, or *nitrat of potass*. As this salt, known also by the name of saltpetre, is produced naturally in considerable quantities, particularly in Egypt, it is highly probable that the antients were acquainted with it; but scarcely any thing certain can be collected from their writings. If Pliny mentions it at all, he confounds it with soda, which was known by the names of nitron and nitrum. It is certain, however, that it has been known in the East from time immemorial. Roger Bacon mentions this salt in the 13th century under the name of nitre.

No phenomenon has excited the attention of chemical philosophers more than the continual reproduction of nitre in certain places after it had been extracted from them. Prodigious quantities of this salt are necessary for the purposes of war; and as nature has not laid up great magazines of it, as she has of some other salts, this annual reproduction is the only source from which it can be procured. It became therefore of the utmost consequence, if possible, to discover the means which nature employed in forming it, in order to enable us to imitate her processes by art, or at least to accelerate and facilitate them at pleasure. Numerous attempts accordingly have been made to explain and to imitate these processes.

Lemery the younger advanced, that all the nitre obtained exists previously in animals and vegetables; and that it is formed in these substances by the processes of vegetation and animalization. But it was soon discovered that nitre exists, and is actually formed, in many places where no animal nor vegetable substance had been decomposed; and consequently this theory was as untenable as the former. So far indeed is it from being true that nitre is formed by these processes alone, that the quantity of nitre in plants has been found to depend entirely on the soil in which they grow.

At last, by the numerous experiments of several French philosophers, particularly by those of Thouvenel, it was discovered that nothing else is necessary for the production of nitre than a basis of lime, heat, and an open but not too free communication with dry atmospheric air. When these circumstances combine the acid is first formed, and afterwards the alkali makes its appearance. How the air furnishes materials for this production is easily explained, now that the component parts of the nitric acid are known to be oxygen and azote: but how lime contributes to their union it is not so easy to see. The appearance of the potass is equally extraordinary. If any thing can give countenance to the hypothesis that potass is composed of lime and azote, it is this singular fact.

Nitre is found abundantly on the surface of the earth in India, South America, and even in some parts of Spain. In Germany and France it is obtained by means of artificial nitre-beds. These consist of the refuse of animal and vegetable bodies undergoing putrefaction, mixed with calcareous and other earths. It has been ascertained that if oxygen gas is presented to azote at the instant of its disengagement, nitric acid is formed. This seems to explain the origin of the acid in these beds. The azote disengaged from these putrefying animal substances combines with the oxygen of the air. The potass is probably furnished, partly at least, by the vegetables and the soil.

The nitre is extracted from these beds by lixiviating the earthy matters with water. This water, when sufficiently impregnated, is evaporated, and a brown-coloured salt obtained, known by the name of crude nitre. It consists of nitre, common salt, nitrat of lime, and various other salts. The foreign salts are either separated by repeated crystallizations, or by washing the salt repeatedly with small quantities of water; for the foreign salts being more soluble are taken up first.

Nitre, when slowly evaporated, is obtained in six-sided prisms, terminated by six-sided pyramids; but for most purposes it is preferred in an irregular mass, because in that state it contains less water. The primitive form of its crystals, according to Hauy, is a rectangular octahedron, composed of two four-sided pyramids applied base to base; two of the sides are inclined to the other pyramid at an angle of 120°; the other two at an angle of 111°. The form of its integrant particles is the tetrahedron. The six-sided prism is the most common form which it assumes. Sometimes, instead of six-sided pyramids, these prisms are terminated by 18 facets, disposed in three ranges of six, as if three truncated pyramids were piled on each other; sometimes it crystallizes in tables.

The specific gravity of nitre is 1.9369. Its taste is sharp, bitterish, and cooling. It is very brittle. It is soluble in seven times its weight of water at the temperature of 60°, and in nearly its own weight of boiling water. It is not altered by exposure to the air.

When the solution of nitre is exposed to a boiling heat, part of the salt is evaporated along with the water, as Wallerius, Kirwan, and Lavoisier, observed successively. When exposed to a strong heat it melts, and congeals by cooling into an opaque mass, which has been called mineral crystal. Whenever it melts it begins to disengage oxygen; and by keeping it in a red heat about the third of its weight of that gas may be obtained: towards the end of the process azotic gas is disengaged. If the heat is continued long enough the salt is completely decomposed, and pure potass remains behind.

It detonates more violently with combustible bodies than any of the other nitrats. When mixed with one-third part of its weight of charcoal, and thrown into a red-hot crucible, or when charcoal is thrown into red-hot nitre, detonation takes place, and one of the most brilliant combustions that can be exhibited. The residuum is carbonat of potass. It was formerly called nitre fixed by charcoal. A still more violent detonation is produced by using phosphorus instead of charcoal. When a mixture of nitre and phosphorus is struck smartly with a hot hammer a very violent detonation is produced.

Nitre oxidizes all the metals at a red heat, even gold and platinum.

Nitre, according to Bergman, is composed of

31	acid
61	potass
8	water.
100	

According to the latest experiments of Kirwan, after being dried in the temperature of 70°, it is composed of

44.0	acid
51.8	potass
4.2	water.
100.0	

Nitre is decomposed by the following salts:

1. Sulphats of soda, ammonia, magnesia, alumina.
2. Muriat and acetat of barytes.

One of the most important compounds formed by means of nitre is gunpowder, which has completely changed the modern art of war. See GUNPOWDER.

NITRIC ACID seems to have been first obtained in a separate state by Raymond Lully, who was born at Majorca in 1235. He procured it by distilling a mixture of nitre and clay. It was afterwards denominated aquafortis, and spirit of nitre. The name nitric acid was first given it in 1787 by the French chemists; it was immediately before called nitrous acid.

1. It is generally obtained in large manufactories by distilling a mixture of nitre and clay; but the acid procured by this process is weak and impure. Chemists generally prepare it by distilling three parts of nitre and one of sulphuric acid in a glass retort. The neck of the retort must be luted into a receiver, from which there passes a glass tube into a bottle with two mouths, containing a little water, and furnished with a tube of safety; which is a tube open at its upper end, and having its lower end plunged in water. The water prevents any communication between the external air and the inside of the apparatus. If a vacuum happens to be formed within the vessels, the external air reaches down through the tube, and prevents any injury to the vessels. On the other hand, if air is generated in the vessels it forces the water up the tube, the height of which becomes thus the measure of the elasticity of the air in the vessels. By this contrivance the apparatus is in no danger of being broken, which otherwise might happen. From the other mouth of this bottle there passes a tube into a pneumatic apparatus, to collect the gas which is evolved during the process. The retort is to be heated gradually almost to redness. The nitric acid comes over, and is condensed in the receiver; while the common air of the vessels, and a quantity of oxygen gas which is evolved, especially towards the end of the process, passes into the pneumatic apparatus, and the water in the bottles is impregnated with some acid which is not condensed in the receiver.

The acid thus obtained is of a yellow colour, and almost always contains muriatic and sometimes sulphurous acid. These may be removed by distilling it over again with a moderate heat, and changing the receiver after the first portion, which contains all the foreign acids, has passed. It still contains a quantity of nitrous gas, to which it owes its colour and the red fumes which it exhales. This gas may also be expelled by the application of heat. Pure nitric acid remains behind, transparent and colourless, like water.

When newly prepared in this manner it is a liquid as transparent and colourless as water; but the affinity between its component parts is so weak, that the action of light is sufficient to drive off a part of its oxygen in the form of gas; and thus, by converting it partly into nitrous gas, to make it assume a yellow colour. Its taste is exceedingly acid and peculiar. It is very corrosive, and tinges the skin of a yellow colour, which does not disappear till the epidermis comes off. It is constantly emitting white fumes which have an acrid disagreeable odour.

It has a strong affinity for water, and has never yet been obtained except mixed with that liquid. When concentrated it attracts moisture from the atmosphere, but not so powerfully as sulphuric acid. It also produces heat when mixed with water, owing evidently to the concentration of the water.

The specific gravity of the strongest nitric acid that can be procured is 1.583; but at the temperature of 60°, Mr. Kirwan could not procure it stronger than 1.5543.

As this liquid acid is a compound of two ingredients, namely, pure nitric acid and water, it becomes an object of the greatest consequence to ascertain the proportion of each of these parts. This problem has lately occupied the attention of Mr. Kirwan, who has endeavoured to solve it in the following manner:

He dried a quantity of crystallized carbonat of soda in a red heat, and dissolved it in water, in such a proportion that 367 grains of the solution contained 50.05 of alkali. He saturated 367 grains of this solution with 147 grains of nitric acid, the specific gravity of which was 1.2754; and which he ascertained to contain 45.7 per cent. of acid, of the specific gravity 1.5543, chosen by him as a standard. The carbonic acid driven off amounted to 14 grains. On adding 939 grains of water the specific gravity of the solution, at the temperature of 58.5°, was 1.0401. By comparing this with a solution of nitrat of soda, of the same density, he found that the salt contained in it amounted to $\frac{1}{16.901}$ of the whole. There was an excess of acid of about two grains. The weight of the whole was 1439 grains: the quantity of salt consequently was $\frac{1439}{16.901} = 85.142$ grains. The quantity of alkali was $50.05 - 14 = 36.05$. The quantity of standard acid employed was 66.7. The whole therefore amounted to 102.75 grains; but as only 85.142 grains entered into the composition of the salt, the remaining 17.608 must have been pure water mixed with the nitric acid. But if 66.7 of standard acid contain 17.608 of water, 100 parts of the same acid must contain 26.38. One hundred parts of standard nitric acid, therefore, are composed of 73.62 parts of pure nitric acid and 26.38 of water.

Mr. Davy considers as pure acid the permanently elastic vapour or gas formed by saturating nitrous gas with oxygen gas. This gas is of a pale-yellow colour, and a specific gravity 2.44 times that of air. It is not pure acid, containing undoubtedly a portion of nitrous gas. The following table exhibits the proportion of this acid contained in nitric acid of different densities, according to the experiments of that ingenious chemist:

100 Parts Nitric Acid, of Sp. Gr.	True Acid.	Water.
1.5040	91.55	8.45
1.4475	80.39	19.61
1.4285	71.65	28.35
1.3906	62.96	37.04
1.3551	56.88	43.12
1.3186	52.03	47.97
1.3042	49.04	50.96
1.2831	46.03	53.97
1.2090	45.27	54.73

When nitric acid is exposed to the action of heat it boils at the temperature of 248, and evaporates completely without alteration; but when made to pass through a red-hot porcelain tube it is decomposed, and converted into oxygen and azotic gas. When cooled down to —66 it begins to congeal; and when agitated it is converted into a mass of the consistence of butter.

Oxygen gas has no action whatever on nitric acid; but all the simple combustibles decompose it, unless we are to except the diamond. When poured upon sulphur or phosphorus at a high temperature it sets them on fire; but at a moderate temperature it converts them slowly into acids, while nitrous gas is exhaled. It inflames charcoal also at a high temperature; and even at the common temperature, provided the charcoal is perfectly dry and minutely divided. Hydrogen gas produces no change on it at the temperature of the atmosphere; but when passed along with it through a red-hot porcelain tube it detonates with great violence; water is formed, and azotic gas evolved.

When this acid is poured upon oils it sets them on fire. This is occasioned by a decomposition both of the acid and oil. The oxygen of the acid combines with the carbon and with the hydrogen of the oils, and at the same time lets go a quantity of caloric. Hence we see that the oxygen which enters into the composition of the nitric acid still contains a great deal of caloric; a fact which is confirmed by a great number of other phenomena. The combustion of oils by this acid was first taken notice of by Borrichius and Slare; but it is probable that Homberg communicated it to Slare. In order to set fire to the fixed oils it must be mixed with some sulphuric acid; the reason of which seems to be, that these oils contain water, which must be previously removed. The sulphuric acid combines with this water, and allows the nitric acid, or rather the oil and nitric acid together, to act. The drying oils do not require any sulphuric acid: they have been boiled, and consequently deprived of all moisture.

Azote has no action on nitric acid; but muriatic acid decomposes it by combining with a portion of its oxygen nitrous gas and oxymuriatic gas being evolved.

It is capable of oxidizing all the metals, except gold, platinum, and titanium. It appears, from the experiments of Scheffer, Bergman, Sage, and Tillet, that nitric acid is capable of dissolving (and consequently of oxidizing) a very minute quantity even of gold.

It even sets fire to zinc, bismuth, and tin, if it is poured on them in fusion, and to filings of iron if they are perfectly dry.

Nitric acid combines with alkalies, earths, and the oxides of metals, and forms compounds, which are called nitrats.

The order of its affinities is as follows:

Barytes,
Potass,
Soda,
Strontian,
Lime,
Magnesia,
Ammonia,
Glucina,
Alumina,
Zirconia.

Nitric acid is one of the most important instruments of analysis which the chemist possesses; nor is it of inferior consequence when considered in a political or commercial view, as it forms one of the most essential ingredients of gunpowder. Its nature and composition accordingly have long occupied the attention of philosophers; and from their experiments it appears, that nitric acid is composed of azote and oxygen; consequently nitrous gas is also composed of the same ingredients. And as nitrous gas absorbs oxygen, even from common air, and forms with it nitric acid, it is evident that nitric acid contains more oxygen than nitrous gas. But it is exceedingly difficult to ascertain the exact proportions of the component parts of this acid. Lavoisier concluded, from his experiments on the decomposition of nitre by charcoal, that nitric acid is composed of one part of azote and four parts of oxygen. But Davy has shewn that this decomposition is more complicated than had been supposed; and that Lavoisier's experiments by no means warrant the conclusion which he drew from them. Cavendish, on the other hand, concluded, from his experiments, that the acid which he formed, by combining together azote and oxygen by means of electricity, is composed of one part of azote and 2.346 of oxygen. With this result the late experiments of Mr. Davy corresponded very nearly. He formed his standard acid by combining together known quantities of nitrous gas and oxygen. According to him 100 parts of pure nitric acid are composed of

29.5 azote
70.5 oxygen

100.0;

or 1 part of azote, and 2.39 of oxygen.

Nitric acid is seldom in a state of absolute purity, holding usually a certain portion of nitrous gas in solution. In this state it is distinguished by the name of nitrous acid; a compound of considerable importance. See Nitrous Acid.

NITRITES, are salts formed from nitrats, saturated with nitrous gas. See Nitrats.

The existence of these salts was first pointed out by Bergman and Scheele; the two philosophers to whom we are indebted for the first precise notions concerning the difference between nitric and nitrous acids. They cannot be formed by combining directly nitrous acid with the different earthy and alkaline bases; nor have any experiments made to combine nitrous gas with the nitrats been attended with success.

The only method of obtaining these salts at present known, is that which was long ago pointed out by Bergman and Scheele. It consists in exposing a nitrat to a pretty strong heat till a quantity of oxygen gas is disengaged from it. What remains in the retort after this process is a nitrite; but the length of time necessary for producing this change has not yet been ascertained with any degree of precision. If the heat is applied too long the nitrat will be totally decomposed, and nothing but the base will remain, as happened to some of the French chemists on attempting to repeat the process of Bergman and Scheele.

Nitrite of potass is the only salt formed by this process, of which an account has been given. Scheele's process for obtaining it is as follows: Fill a small retort with nitre, and keep it red-hot for half an hour. When it is allowed to cool it is found in the state of a nitrite. It deliquesces when exposed to the air; and red vapours of nitrous acid are exhaled when any other acid is poured upon it.

As the nitrites have never been examined by chemists, and as it has not even been determined whether any considerable number of the nitrats can be converted into these salts, it would be in vain, in the present state of our knowledge, to attempt a particular description of them. It may, however, be considered as exceedingly probable that no such salts as the nitrites of ammonia, glucina, yttria, alumina, and zirconia, exist or can be formed, at least by the process of Scheele and Bergman; for the nitrats with these bases are decomposed completely by the action of a heat too moderate to hope for the previous emission of oxygen gas.

From the few observations that have been made, it may be concluded that the nitrites are in general deliquescent, very soluble in water, decomposible by heat as well as nitrats; that their taste is cooling like that of the nitrats, but more acrid and nitrous: that by exposure to the air they are gradually converted into nitrats by absorbing oxygen; but this change takes place exceedingly slowly.

NITRO-MURIATIC acid. When muriatic acid is mixed with nitric acid, the mixture is nitro-muriatic acid, which was formerly known by the name of aqua-regia.

NITROUS ACID. The liquid at present called nitrous acid by chemists, may be formed by causing nitrous gas to pass through nitric acid. The gas is absorbed, and the acid assumes a yellow colour; and its specific gravity is diminished. It is then denominated nitrous acid. It is always in this state that it is obtained by distilling a mixture of sulphuric acid and nitre. The acid of commerce is always nitrous acid. The nitric and nitrous acids were first distinguished with accuracy by Scheele.

The nature of nitrous acid was first investigated by Dr. Priestley, who demonstrated, by very decisive experiments, that it is a compound of nitric acid and nitrous gas. This opinion was embraced, or rather it was first fully developed, by Morveau. But the theory of Lavoisier, which supposed the difference between nitric and nitrous acids to depend merely on the first containing a greater proportion of oxygen than the second, for some time drew the attention of chemists from the real nature of nitrous acid. Raymond published a dissertation in 1796, to demonstrate the truth of the theory of Priestley and Morveau; and the same thing has been done still more lately by Messrs. Thomson and Davy. At present it is allowed by every one, that nitrous acid is merely nitric acid more or less impregnated with nitrous gas.

This being the case, and nitric acid being capable of absorbing very different proportions of nitrous gas, it is evident that there must be a great variety of nitrous acids, differing from each other in the proportion of nitrous gas which they contain; unless we choose to confine the term nitrous acid to the compound formed by saturating nitric acid completely with nitrous gas.

When nitrous gas is placed in contact with nitric acid, the acid absorbs it slowly, and acquires first a pale-yellow colour, then a bright yellow. When a considerable portion more of nitrous gas is absorbed, the acid becomes dark orange, then olive, which increases in intensity with the gas absorbed; then it becomes of a bright green; and, lastly, when fully saturated, it becomes blue-green. Its volume and its volatility also increase with the quantity of gas absorbed; and when fully saturated it assumes the form of a dense vapour, of an exceedingly suffocating odour, and difficultly condensible by water. In this state of saturation it is distinguished by Dr. Priestley by the name of nitrous acid vapour. It is of a dark-red colour, and passes through water partly without being absorbed. The quantity of nitrous gas absorbed by nitric acid is very great. Dr. Priestley found, that a quantity of acid, equal in bulk to four pennyweights of water, absorbed 130 ounce-measures of gas without being saturated. The component parts of nitrous acid, of different colours and densities, may be seen in the following table, drawn up by Mr. Davy, from experiments made by him on purpose, with much precision:

100 Parts.	Sp. Grav.	Component Parts.		
		Nitric Acid.	Water.	Nitrous Gas.
Solid nitric acid	1.504	91.55	8.45	—
Yellow nitrous	1.502	90.5	8.3	2
Bright yellow	1.500	88.94	8.10	2.96
Dark orange	1.480	86.84	7.6	5.56
Light olive	1.479	86.00	7.55	6.45
Dark olive	1.478	85.4	7.5	7.1
Bright green	1.476	84.8	7.44	7.76
Blue green	1.475	84.6	7.4	8.00

The colour of nitrous acid depends, in some measure, also on the proportion of water which it contains. When to yellow nitrous acid concentrated, a fourth part by weight of water is added, the colour is changed to a fine green; and when equal parts of water are added, it becomes blue. Dr.

Priestley observed, that water impregnated with this acid in the state of vapour, became first blue, then green, and lastly yellow. A green nitrous acid became orange-coloured while hot, and retained a yellow tinge when cold. A blue acid became yellow on being heated in a tube hermetically sealed. An orange-coloured acid, by long keeping, became green, and afterwards of a deep blue; and when exposed to air resumed its original colour. When nitrous acid is exposed to heat the nitrous gas is expelled, and nitric acid remains behind. The gas, however, carries along with it a quantity of acid, especially if the acid is concentrated. But nitrous acid vapour is not altered in the least by exposure to heat.

It is not altered by oxygen gas, common air, nor by azotic gas.

The simple combustibles and metals act upon it precisely as on nitric acid. It answers much better than nitric acid for inflaming oils and other similar bodies.

It converts sulphurous and phosphorous acids into sulphuric and phosphoric.

Nitrous acid vapour is absorbed by sulphuric acid, but seemingly without producing any change; for when water is poured into the mixture, the heat produced expels it in the usual form of red fumes. The only singular circumstance attending this impregnation is, that it disposes the sulphuric acid to crystallize.

NOBILITY, a quality that ennobles, and raises a person possessed of it above the rank of a commoner.

The civil state of England consists of the nobility and commonalty. The nobility are all those who are above the degree of knight, under which term is included that of a baronet; namely, dukes, marquises, earls, viscounts, and barons. 1 Black. 396.

NOCTURNAL, Nocturlabium, an instrument chiefly used at sea, to take the altitude or depression of some stars about the pole, in order to find the latitude, and hour of the night.

Some nocturnals are hemispheres, or planispheres, on the plane of the equinoctial. Those commonly in use among seamen are two; the one adapted to the polar star, and the first of the guards of the little bear; the other to the pole-star, and the pointers of the great bear.

This instrument consists of two circular plates (see Plate Miscel. figure 173), applied to each other. The greater, which has a handle to hold the instrument, is about two inches and a half in diameter, and is divided into twelve parts, agreeing to the twelve months, and each month subdivided into every fifth day; and so that the middle of the handle corresponds to that day of the year wherein the star here regarded has the same right ascension with the sun. If the instrument is fitted for two stars, the handle is made moveable. The upper left circle is divided into twenty-four equal parts for the twenty-four hours of the day, and each hour subdivided into quarters. These twenty-four hours are noted by twenty-four teeth, to be told in the night. Those at the hours 12 are distinguished by their length. In the centre of the two circular plates is adjusted a long index, A, moveable upon the upper plate; and the three pieces, viz. the two circles and index, are joined by a rivet which is pierced through the centre with a hole, through which the star is to be observed.

To use the nocturnal.—Turn the upper plate till the long tooth, marked 12, is against the day of the month on the under plate: then, bringing the instrument near the eye, suspend it by the handle with the plane nearly parallel to the equinoctial; and viewing the pole-star through the hole of the centre, turn the index about till, by the edge coming from the centre, you see the bright star, or guard, of the little bear (if the instrument is fitted to that star): then that tooth of the upper circle, under the edge of the index, is at the hour of the night on the edge of the hour-circle: which may be known without a light, by counting the teeth from the longest, which is for the hour 12.

NODE. See Surgery.

NODES. See Astronomy.

NOETIANS, in church history, christian heretics in the 3d century, followers of Noetius, a philosopher of Ephesus, who it is said pretended that he was another Moses, sent by God, and that his brother was a new Aaron; his doctrine consisted in affirming that there was but one person in the Godhead, and that the Word and the Holy Spirit were but external denominations given to God in consequence of different operations; that as creator he is called Father; as incarnate, Son; and as descending on the apostles, Holy Ghost.

NOLANA, a genus of the monogynia order, in the pentandria class of plants, and in the natural method ranking under the 41st order, asperifoliæ. The corolla is campanulated; the style situated betwixt the germens; the seeds are bilocular, and resemble berries. There is one species, an annual of Peru.

NOLLE PROSEQUI, is used where the plaintiff proceeds no farther in his action, and may be as well before as after a verdict, and is stronger against a plaintiff than a nonsuit, which is only a default in appearance; but this is a voluntary acknowledgment that he has no cause of action. Impey's B. R.

NOMBRIL POINT, in heraldry, is the next below the fess-point, or the very centre of the escutcheon.

NOME, or Name, in algebra, denotes any quantity with a sign prefixed or added to it, whereby it is connected with some other quantity, upon which the whole becomes a binomial, trinomial, or the like: thus $a+b$ is a binomial, $a+b+c$ is a trinomial, whose respective names or nomes are a and b for the first, and a, b, and c, for the second. See Algebra.

NOMINATIVE, in grammar, the first case in nouns which are declinable.

NON-APPEARANCE, a default in not appearing in a court of judicature. Attorneys subscribing warrants for appearing in court are liable to attachment and fine for non-appearance. If a defendant does not appear and find bail upon a scire facias and rule given, jugment may be had against him.

Non compos mentis, in law, is used to denote a person's not being of sound memory and understanding. Of these persons there are four different kinds, an ideot, a madman, a lunatic who has lucid intervals, and a drunkard who deprives himself of reason by his own act and deed. In all these cases except the last, one that is non compos mentis shall not lose his life for felony or murder; but the drunkard can have no indulgence on account of the loss of his reason, for, in the eye of the law, his drunkenness does not extenuate but aggravate his offence.

Non est inventus, is a sheriff's return to a writ, that the defendant is not to be found.

Non-naturals, in medicine, so called because by their abuse they become the causes of diseases. See Medicine. The old physicians have divided the non-naturals into 6 classes, viz. the air, meats and drinks, sleep and watching, motion and rest, the passions of the mind, the retentions, and excretions.

Non-pros. If the plaintiff neglects to deliver a declaration for two terms after the defendant appears, or is guilty of other delays or defaults against the rules of law in any subsequent stage of the action, he is adjudged not to pursue his remedy as he ought; and thereupon a nonsuit or non prosequitur is entered, and he is then said to be non-pros'd. 3 Black. 395.

Non-residence. See Residence.

NONAGESIMAL, or *nonagesimal degree*, called also the midheaven, is the highest point, or 90th degree, of the ecliptic, reckoned from its intersection with the horizon at any time; and its altitude is equal to the angle that the ecliptic makes with the horizon at their intersection, or equal to the distance of the zenith from the pole of the ecliptic. It is much used in the calculation of solar eclipses.

NONAGON, a figure having nine sides and angles. In a regular nonagon, or that whose angles and sides are all equal, if each side is 1, its area will be $6.1818242 + \frac{9}{4}$ of $70°$, to the radius 1.

NONIUS. See Vernier.

NONSUIT, in law, is where a person has commenced an action, and at the trial fails in his evidence to support it, or has brought a wrong action. There is this advantage attending a nonsuit, that the plaintiff, though he pays costs, may afterwards bring another action for the same cause, which he cannot do after a verdict against him. Tidd's K. B. Practice.

NONES, *nonæ*, in the Roman calendar, the fifth day of the months January, February, April, June, August, September, November, and December; and the seventh of March, July, and October. March, May, July, and October, had six days in their nones; because these alone, in the antient constitution of the year by Numa, had 31 days apiece, the rest having only 29, and February 30: but when Cæsar reformed the year, and made other months containing 31 days, he did not allot them six days of nones.

NORROY, the title of the third of the three kings at arms. See Heraldry.

NORMAL, a perpendicular forming with another line a right angle.

NORWAY RAT. See Mus.

NOSE. See Anatomy.

NOTARIAL ACTS, are those acts, in the civil law, which require to be done under the seal of a notary, and which are admitted as evidence in foreign courts.

NOTARY, is a person duly appointed to attest deeds and writings; he also protests and notes foreign and inland bills of exchange and promissory notes, translates languages and attests the same, enters and extends ship's protests, &c.

NOTATION, in arithmetic and algebra, the method of expressing numbers or quantities by signs or characters appropriated for that purpose. See ALGEBRA, ARITHMETIC, CHARACTER, &c.

NOTATION, in music, the manner of expressing, or representing by characters, all the different sounds used in music. The antient notation was very different from that of the moderns. The Greeks employed for this purpose the letters of their alphabet, sometimes placing them erect, and sometimes inverting, mutilating, and compounding them in various manners, so as to represent by them all the different tones or chords used in their system. By a treatise of Alypius, professedly written to explain the Greek characters, we find that they amounted to no less a number than 1240. These were, however, rejected afterwards by the Latins, who introduced letters from their own alphabet, A, B, C, D, E, F, G, H, I, K, L, M, N, O, P, fifteen in number, and by which they expressed the sounds contained in the bisdiapason. For the great improvement upon this notation, which at length took place, and which is in part adopted at the present day, we are indebted to St. Gregory, the first pope of that name; who reflecting that in the bisdiapason, the sounds after Lichanos Meson, or the middle tone, were but a repetition of those which preceded, and that every septenary in progression was precisely the same, reduced the number of letters to seven, viz. A, B, C, D, E, F, G: but to distinguish the second septenary from the first, the second was denoted by the small, and not the capital, Roman letters; and when it became necessary to extend the system farther, the small letters were doubled thus, aa, bb, cc, dd, ee, ff, gg. The stave, consisting of a variable number of parallel lines, the application of which some attribute to Guido, was afterwards introduced; and this was again meant to be improved upon by the adoption of small points, commas, accents, and certain little oblique strokes, occasionally interspersed in the stave, while also two colours, yellow and red, were used; a yellow line signifying the letter or note C, and a red line denoting that of F. Two methods of notation were long after employed for the viol and other stringed instruments, which were distinguished by the terms lyra-way and gamut-way; with this exception, that the literal notation for the lute is constantly called the tablature; concerning which, as also the notation by letters in general, it may be observed that they are a very inartificial practice, as was also the old method of notation for the flute and flageolet by dots.

NOTE is a minute, or short writing, containing some article of business; in which sense we say, promissory note, note of hand, bank note. See BILLS of EXCHANGE.

NOTES, in music, characters which by their various forms and situations on the staves, indicate the duration as well as the gravity or acuteness of the several sounds of a composition.

NOTICE, in law, is the making something known that a man was or might be ignorant of before, and it produces divers effects; for by it the party that gives the same shall have some benefit, which otherwise he should not have had: and by this means the party to whom the notice is given is made subject to some action or charge, that otherwise he would not have been liable to, and his estate in danger of prejudice. Co. Lit. 309.

The plaintiff and defendant are both bound at their peril to take notice of the general rules of the practice of the court; but if there is a special particular rule of court made for the plaintiff, or for the defendant, he for whom the rule is made ought to give notice of this rule to the other; or else he is not bound generally to take notice of it, nor shall be in contempt of the court although he does not obey it. 2 L. P. R. 204.

NOTONECTA, a genus of insects of the order hemiptera. The generic character is, snout inflected; antennæ shorter than thorax; wings coriaceous on the upper part, and crossed over each other; hind feet edged with hairs, and formed for swimming. The principal species of this are,

1. The notonecta glauca, a very common aquatic insect, inhabiting stagnant waters; and generally measuring about three parts of an inch in length. Its colour is grey-brown, and the upper wings are marked along the edges by a row of minute black specks. This insect is usually seen swimming on its back, in which situation it bears a most striking resemblance to a boat in miniature, the hind legs acting like a pair of oars, and impelling the animal at intervals through the water. It preys on the smaller inhabitants of the water, and flies only by night.

2. Notonecta striata, is much smaller than the preceding, not measuring more than a quarter of an inch in length, and is of a yellowish-grey colour, with numerous transverse undulated black lines or streaks: it is found in stagnant waters.

3. Notonecta minutissima, is an extremely small species, with grey wings, marked by longitudinal dusky spots: like the two former it is an inhabitant of stagnant waters, but is far less frequently observed than the rest, on account of its very small size. There are 17 species.

NOTOXUS, a genus of insects of the coleoptera order. The generic character is, antennæ filiform; feelers four, hatchet-shaped; jaw one-toothed; thorax a little narrowed behind. There are 13 species, found in Europe and Asia.

NOVATIANS, a christian sect which sprang up in the third century, so called from Novatian, a priest of Rome, or Novatus, an African bishop, who separated from the communion of pope Cornelius, whom Novatian charged with a criminal lenity towards those who had apostatised during the persecution of Decius. He denied the church's power of remitting mortal sins.

NOVEL, in the civil law, a term used for the constitutions of several emperors, as of Justin, Tiberius, Leo, and more particularly for those of Justinian. The constitutions of Justinian were called novels, either from their producing a great alteration in the face of the antient law, or because they were made on new cases, and after the revisal of the antient code, compiled by the order of that emperor. Thus the constitutions of the emperors Theodosius, Valentinian, Marcian, &c. were also called novels, on account of their being published after the Theodosian code.

NOUN, in grammar, a part of speech, which signifies things without any relation to time; as a man, a house, sweet, bitter, &c.

NUCLEUS, in general, denotes the kernel of a nut, or even any seed inclosed within a husk. The term nucleus is also used for the body of a comet, otherwise called its head.

NUDE CONTRACT, a bare promise, without any consideration, and therefore void.

NUISANCE, signifies generally any thing that works hurt, inconvenience, or damage, to the property or person of another. Nuisances are of two kinds, public or private nuisance, and either affect the public or the individual. The remedy for a nuisance is by action on the case for damages. Every continuance of a nuisance is a fresh nuisance, and a fresh action will lie.

NUMBER, *kinds and distinctions of.* Mathematicians, considering number under a great many relations, have established the following distinctions. Broken numbers are the same with fractions. Cardinal numbers are those which express the quantity of units, as 1, 2, 3, &c. whereas ordinal numbers are those which express order, as 1st, 2d, 3d, &c. Compound number, one divisable by some other number besides unity; as 12, which is divisible by 2, 3, 4, and 6. Numbers, as 12 and 15, which have some common measure besides unity, are said to be compound numbers among themselves.

Cubic number is the product of a square number by its root: such as 27, as being the product of the square number 9, by its root 3. All cubic numbers whose root is less than 6, being divided by 6, the remainder is the root itself: thus $27 \div 6$ leaves the remainder 3, its root; 216, the cube of 6, being divided by 6, leaves no remainder; 343, the cube of 7, leaves a remainder 1, which added to 6, is the cube root; and 512, the cube of 8, divided by 6, leaves a remainder 2, which added to 6, is the cube root. Hence the remainders of the divisions of the cubes above 216, divided by 6, being added to 6, always gives the root of the cube so divided, till that remainder is 5, and consequently 11 the cube-root of the number divided. But the cube number above this being divided by 6, there remains nothing, the cube-root being 12. Thus the remainders of the higher cubes are to be added to 12, and not to 6, till you come to 18, when the remainder of the division must be added to 18; and so on ad infinitum.

Determinate number, is that referred to some given unit, as a ternary or three: whereas an indeterminate one, is that referred to unity in general, and is called quantity.

Homogeneal numbers, are those referred to the same unit; as those referred to different units are termed heterogeneal.

Whole numbers, are otherwise called integers. See INTEGER.

Rational number, is one commensurable with unity; as a number incommensurable with unity, is termed irrational or a surd. See SURD.

In the same manner a rational whole number, is that whereof unity is an aliquot part; a rational broken number, that equal to some aliquot part of unity; and a rational mixed number, that consisting of a whole number and a broken one.

Even number, that which may be divided into two equal parts without any fraction, as 6, 12, &c. The sum, difference, and product, of any number of even numbers, is always an even number.

An evenly even number, is that which may be measured, or divided, without any remainder, by another even number, as 4 by 2.

An unevenly even number, when a number may be equally divided by an uneven number, as 20 by 5.

Uneven number, that which exceeds an even number, at least by unity, or which cannot be divided into two equal parts, as 3, 5, &c.

The sum or difference of two uneven numbers makes an even number; but the factum of two uneven ones makes an uneven number.

If an even number is added to an uneven one, or if the one is substracted from the other, in the former case the sum, in the latter the difference, is an uneven number; but the factum of an even and uneven number is even.

The sum of any even number of uneven numbers is an even number; and the sum of any uneven number of uneven numbers is an uneven number.

Primitive or prime numbers, are those only divisible by unity, as 5, 7, &c. And prime numbers among themselves, are those which have no common measure besides unity, as 12 and 19.

Perfect number, that whose aliquot parts, added together, make the whole number, as 6, 28; the aliquot parts of 6 being 3, 2, and 1 = 6; and those of 28, being 14, 7, 4, 2, 1, = 28.

Imperfect numbers, those whose aliquot parts, added together, make either more or less than the whole. And these are distinguished into abundant and defective; an instance in the former case is 12, whose aliquot parts 6, 4, 3, 2, 1 make sixteen; and in the latter case 16, whose aliquot parts 8, 4, 2, and 1, make but 15.

Plain number, that arising from the multiplication of two numbers, as 6, which is the product of 3 by 2; and these numbers are called the sides of the plane.

Square number, is the product of any number multiplied by itself; thus 4, which is the factum of 2 by 2, is a square number.

Every square number added to its root makes an even number.

Polygonal, or polygonous numbers, the sums of arithmetical progressions beginning with unity; these, where the common difference is 1, are called triangular numbers; where 2, square numbers; where 3, pentagonal numbers; where 4, hexagonal numbers; where 5, heptagonal numbers, &c. See POLYGONAL.

Pyramidal numbers: the sums of polygonous numbers, collected after the same manner as the polygons themselves, and not gathered out of arithmetical progressions, are called first pyramidal numbers; the sums of the first pyramidals are called second pyramidals, &c.

If they arise out of triangular numbers, they are called triangular pyramidal numbers; if out of pentagons, first pentagonal pyramidals.

From the manner of summing up polygonal numbers, it is easy to conceive how the prime pyramidal numbers are found, viz. $\frac{(a-2)\,n^3 + 3\,n^2 - (a-5)\,n}{6}$ expresses all the prime pyramidals.

NUMBER, in grammar, a modification of nouns, verbs, &c. to accommodate them to the varieties in their objects, considered with regard to number.

NUMERAL LETTERS, those letters of the alphabet which are generally used for figures as I, V, X, L, C, D, M. See ARITHMETIC, CHARACTER, &c.

NUMERALS, in grammar, those words which express numbers; as six, eight, ten, &c.

NUMERATION. See ARITHMETIC, CHARACTER, &c.

NUMIDA, in ornithology, a genus belonging to the order of gallinæ. On each side of the head there is a kind of coloured fleshy horn; and the beak is furnished with cere near the nostrils. The species called meleagris, or Guinea hen, is a native of Africa. See Plate Nat. Hist. fig. 298. It is larger than a common hen. Its body is sloped like that of a partridge; and its colour is all over a dark grey, very beautifully spotted with small white specks; there is a black ring round the neck; its head is reddish, and it is blue under the eyes. They naturally herd together in large numbers, and breed up their young in common; the females taking care of the broods of others, as well as of their own. Barbut informs us, that in Guinea they go in flocks of 200 or 300, perch on trees, and feed on worms and grasshoppers; that they are run down and taken by dogs; and that their flesh is tender and sweet, generally white, though sometimes black. They breed very well with us.

The white-breasted one is a mere variety, of which there are many; it is mostly found in Jamaica. The mitred, or numida mitrata, is a different and not a common species; it inhabits Madagascar and Guinea. The third species which Mr. Latham mentions is the crested, or numida cristata. This species likewise inhabits Africa. Buffon, who describes it at great length, calls it la peintade. Linnæus and Gmelin call it Numida meleagris, &c. Ray and Willughby call it gallus and gallina Guineensis, &c. Mr. Pennant contends, and seems to prove, that the pintados had been early introduced into Britain, at least prior to the year 1277. But they seem to have been much neglected on account of the difficulty of rearing them; for they occur not in our antient bills of fare. They have a double caruncle at the chaps, and no fold at the throat.

NUNCIO, or *Nuntio*, an ambassador from the pope to some catholic prince or state; or a person who attends on the pope's behalf at a congress, or an assembly of several ambassadors. The nuncio has a jurisdiction and may delegate judges in all the states where he resides, except in France, where he has no authority but that of a simple ambassador. See AMBASSADOR.

NUNCUPATIVE WILL, denotes a last will or testament, only made verbally, and not put in writing. See WILL and TESTAMENT.

NURSERY, in gardening, is a piece of land set apart for raising and propagating all sorts of trees and plants, to supply the garden and other plantations.

In a nursery for fruit-trees, the following rules are to be observed: 1. That the soil should not be better than that in which the trees are to be planted out for good. 2. That it ought to be fresh, and not such as has been already worn out by trees, or other large growing plants. 3. It ought neither to be too wet, nor too dry, but rather of a middling nature; though, of the two extremes, dry is to be preferred; because, though trees in such a soil do not make so great a progress, yet they are generally sounder, and more disposed to fruitfulness. 4. It must be inclosed in such a manner that neither cattle nor vermin may come in; and so as particularly to exclude hares and rabbits, which, when the ground is covered with snow, are great destroyers of young trees. 5. The ground being inclosed should be carefully trenched about two feet deep; this this should be done in August, that it may be ready for receiving young stocks at the season for planting, which is commonly about the beginning of October: in trenching the ground, you must be careful to cleanse it from the roots of all noxious weeds. 6. The season being come for planting, level down the trenches as equal as possible; and then lay out the ground into quarters, which may be laid out in beds for a seminary, in which you may sow the seeds or stones of fruit. 7. And having provided yourself with stocks, the next year proceed to transplant them, in the following manner: draw a line across the ground intended to be planted, and open a number of trenches exactly straight; then take the stocks out of the seed-beds; in doing which, you should raise the ground with a spade, in order to preserve the roots as entire as possible; prune off the very small fibres, and if there are any that have a tendency to root directly downwards, such roots should be shortened. Then plant them in the trenches, if they are designed for standards, in rows three feet and a half, or four feet, from each other, and a foot and a half distant in the rows; but if for dwarfs, three feet row from row, and one foot in the row, will be a sufficient distance. These plants should by no means be headed, or pruned at top, which will weaken them, and cause them to produce lateral branches. If the winter should prove very cold, lay some mulch on the surface of the ground near their roots, taking care not to let it lie too thick near the stems of the plants, and to remove it as soon as the frost is over. In the summer season destroy the weeds, and dig up the ground every spring between the rows. The second year after planting, such of the stocks as are designed for dwarfs will be fit to bud; but those that are designed for standards should be suffered to grow five or six feet high before they are budded or grafted; for the manner of doing which, see GRAFTING.

As to timber trees, Mr. Miller advises those gentlemen who would have plantations in parks, woods, &c. to make nurseries upon the ground intended for planting, where a sufficient number of the trees may be left standing, after the others have been drawn out to plant in other places.

The ground intended for the flower-nursery should be well situated to the sun; and defended from strong winds by plantations of trees, or by buildings. The soil also should be light and dry, especially for bulbous-rooted flowers; for in this nursery the offsets of all bulbous-rooted flowers should be planted, and remain there till they become blowing roots, when they should be removed into the pleasure-garden, and planted either in beds or borders, according to the goodness of the flowers. These flowers may also be raised in the nursery from seed. The seedling auriculas, polyanthuses, ranunculuses, anemonies, carnations, &c. should be raised in this nursery, where they should be preserved till they have flowered, when all those should be marked that are worthy of being transplanted into the flower-garden: this should be done in their proper seasons; for all these seedling flowers ought not indiscriminately to be exposed to public view in the pleasure-garden, because it always happens, that there are great numbers of ordinary flowers produced among them, which will there make but an indifferent appearance.

NUT. See Corylus.

Nut-galls. See Gallic Acid.

NUTATION, in astronomy, a kind of tremulous motion of the axis of the earth, whereby, in each annual revolution, it is twice inclined to the ecliptic, and as often returns to its former position. Sir Isaac Newton observes, that the moon has the like motion, only very small, and scarcely sensible.

NUTMEG. See Myristica.

NUTRITION. See Digestion, Materia Medica, and Physiology.

NUX VOMICA, a flat, compressed, round fruit, about the breadth of a shilling, brought from India. See Strychnus.

NYCTANTHES, *Arabian Jasmine*, a genus of the monogynia order, in the diandria class of plants; and in the natural method ranking with the 44th order, sepiariæ. The corolla and calyx are octofid: the perianthium dicoccous. There are seven species, the most remarkable of which are: 1. The arbor tristis, or sorrowful tree. This tree, or shrub, the pariaticu of the Bramins, grows naturally in sandy places in India, particularly in the islands of Ceylon and Java, where it is procured in great abundance, and attains the height of 18 or 20 feet. It rises with a four-cornered stem, bearing leaves that are oval, and taper to a point. The flowers, which are white and highly odoriferous, having a sweet delectable smell emulating the best honey, consist of one petal deeply divided into eight parts, which are narrower towards the stalk, and dilated towards the summit. The fruit is dry, capsular, membranaceous, and compressed.

It is generally asserted of this plant, that the flowers open in the evening, and fall off the succeeding day. Fabricius and Paludanus, however, restrict the assertion, by affirming, from actual observation, that this effect is found to take place only in such flowers as are immediately under the influence of the solar rays. Grimmius remarks in his Laboratorium Ceylonicum, that the flowers of this tree afford a fragrant water, which is cordial, refreshing, and frequently employed with success in inflammations of the eyes. The tube of the flower, when dried, has the smell of saffron; and being pounded and mixed with sanders-wood, is used by the natives of the Malabar coast for imparting a grateful fragrancy to their bodies, which they rub or anoint with the mixture.

2. The angustifolia, of which the flowers are white, inexpressibly fragrant, and generally appear in the warm summer-months. Strong loam is its proper soil.

NYMPH, among naturalists, that state of winged insects between their living in the form of a worm, and their appearing in the winged or most perfect state. See Entomology.

NYMPHÆA. See Anatomy.

Nymphæ, the *water-lily*, a genus of the monogynia order, in the polyandria class of plants; and in the natural method ranking under the 54th order, miscellanea. The corolla is polypetalous; the calyx tetraphyllous or pentaphyllous; the berry multilocular and truncated. There are six species, of which the most remarkable are: 1. and 2. The lutea and alba, or yellow and white water-lilies; both of which are natives of Britain, growing in lakes and ditches. Linnæus tells us, that swine are fond of the leaves and roots of the former; and that the smoke of it will drive away crickets and blattæ, or cock-roaches, out of houses. The root of the second has an astringent and bitter taste, like those of most aquatic plants that run deep into the mud. 3. The lotus, with heart-shaped toothed leaves, a plant thought to be peculiar to Egypt, is mentioned by Herodotus. M. Savary mentions it as growing in the rivulets and on the sides of the lakes; and that there are two sorts or varieties of the plant, the one with a white, the other with a blueish flower. "The calyx (he says) blows like a large tulip, and diffuses a sweet smell, resembling that of the lily. The first species produces a round root like that of a potatoe; and the inhabitants of the banks of the lake Menzall feed upon it. The rivulets in the environs of Damietta are covered with this majestic flower, which rises upwards of two feet above the water. 4. In the East and West Indies grows a species of this plant, named nelumbo by the inhabitants of Ceylon. The flowers are large, flesh-coloured, and consist of numerous petals, disposed as in the other species of water-lily, in two or more rows. The seed-vessel is shaped like a top, being broad and circular above, narrow and almost pointed below. It is divided into several distinct cells, which form so many large round holes upon the surface of the fruit, each containing a single seed. With the flower of this plant, which is sacred among the heathens, they adorn the altars of their temples. The stalks, which are used as a pot-herb, are of a wonderful length. The root is very long, extends itself transversely, is of the size of a man's arm, jointed and fibrous, with long intervals between the joints. The fibres surround the joints in verticilli or whorls.

NYSSA, a genus of the order of diœcia, in the polygamia class of plants; and in the natural method ranking under the 12th order, holoraceæ. The hermaphrodite calyx is quinquepartite; there is no corolla; the stamina are five; there is one pistil; the fruit a plum inferior. The male calyx is quinquepartite, no corolla, and ten stamina. There are two species: 1. The integrifolia, entire-leaved; and, 2. The denticulata, or serrated-leaved tupelo.

The entire-leaved tupelo-tree, in its native soil and climate, grows to near 20 feet high; in this country its size varies according to the nature of the soil or situation. In a moist rich earth, well sheltered, it comes to near 20 feet; in others, that are less so, it makes slower progress, and in the end is proportionally lower. The branches are not very numerous; and it rises with a regular trunk, at the top of which they generally grow. In England they seldom produce fruit.

The serrated-leaved tupelo-tree grows usually nearly 30 feet in height; and divides into branches near the top like the other. The leaves are oblong, pointed, of a light-green colour, and come out without order on long footstalks. The flowers come out from the wings of the leaves on long footstalks. They are small, of a greenish-colour; and are succeeded by oval drupes, containing sharp-pointed nuts, about the size of a French olive.

O.

O, the fourteenth letter of our alphabet. As a numeral, it is sometimes used for eleven; and with a dash over it thus $\bar{O}$ for eleven thousand. In the notes of the antients, O. CON. is read opus conductum; O. C. Q. opere consilioque; O. D. M. opera, donum, munus; and O. L. O. opus locatum.

In music, the O, or rather a circle, or double CO, is a note of time called by us a semi-breve; and by the Italians circolo. The O is also used as a mark of triple time, as being the most perfect of all figures.

OAK. See QUERCUS.

OAKAM, old ropes untwisted, and pulled out into loose hemp, in order to be used in caulking the seams, tree-nails, and bends of a ship, for stopping or preventing leaks.

OAR, in navigation, a long piece of wood, for moving a vessel by rowing. Oars for ships are generally cut out of fir-timber, those for barges are made out of New England or Dantzic-rafters, and those for boats, either out of English ash, or fir rafters from Norway.

OAT. See AVENA.

OATH, an affirmation or denial of any thing before one or more persons, who have the authority to administer the same, for the discovery and advancement of truth and right. See AFFIDAVIT.

OBELISK, a truncated, quadrangular, and slender pyramid, raised as an ornament, and frequently charged either with inscriptions or hieroglyphics.

Obelisks appear to be of very great antiquity, and to be first raised to transmit to posterity precepts of philosophy, which were cut in hieroglyphical characters: afterwards they were used to immortalize the great actions of heroes, and the memory of persons beloved. The first obelisk mentioned in history was that of Rameses king of Egypt, in the time of the Trojan war, which was forty cubits high. Phius, another king of Egypt, raised one of forty-five cubits; and Ptolemy Philadelphus, another of eighty-eight cubits, in memory of Arsinoe. Augustus erected one at Rome in the Campus Martius, which served to mark the hours on an horizontal dial, drawn on the pavement. They were called by the Egyptian priests the fingers of the sun, because they were made in Egypt also, to serve as styles or gnomons to mark the hours on the ground. The Arabs still call them Pharoah's needles, whence the Italians call them aguglia, and the French aiguilles.

The proportions in the height and thickness are nearly the same in all obelisks; their height being nine or nine and a half, and sometimes ten times, their thickness; and their diameter at the top never less than half, and never greater than three-fourths, of that at the bottom.

OBLATE, flatted, or shortened; as an oblate spheroid, having its axis shorter than its middle diameter, being formed by the rotation of an ellipse about the shorter axis.

OBLATENESS. See EARTH, figure of.

OBLIGATION, a bond containing a penalty, with a condition annexed, either for payment of money, performance of covenants, or the like. This security is called a specialty. Co. Lit. 172. See BOND, and DEED.

OBLIQUE, in geometry, something aslant, or that deviates from the perpendicular. Thus, an oblique angle, is either an acute or obtuse one; that is, any angle except a right one.

OBLIQUE PLANES. See DIALLING.

OBLONGATA MEDULLA. See ANATOMY.

OBOLUS, in antiquity, an antient Athenian coin, worth a penny farthing. Among antient physicians; obolus likewise denoted a weight, equal to ten grains.

OBOLARIA, a genus of the angiospermia order, in the didynamia class of plants; and in the natural method ranking under the 40th order, personatæ. The calyx is bifid; the corolla campanulated and quadrifid; the capsule unilocular, bivalved, and polyspermous; the stamina rising from the divisions of the corolla. There is one species, a herb of Virginia.

OBSERVATORY, a place destined for observing the heavenly bodies; being generally a building erected on some eminence, covered with a terrace for making astronomical observations.

The principal instruments for a fixed observatory are, a large fixed quadrant, or a circular divided instrument, chiefly for measuring vertical angles; a transit instrument; an equatorial instrument; a chronometer, or regulator; one or more powerful telescopes; a fixed zenith telescope, and a night telescope.

The quadrant, or quarter of a circle, divided into 90°, and each degree subdivided into minutes or smaller parts, has been made of various sizes; some of them having a radius even of eight or nine or more feet in length. When those quadrants do not exceed one or two, or at most three feet, in radius, they are generally fixed upon their particular stands, which are furnished with various mechanical contrivances, that are nesessary to place the plane of the quadrant perpendicular to the horizon, and for all the other necessary adjustments. But large quadrants are fixed upon a strong wall by means of proper clamps; hence they have been commonly called mural quadrants, and are situated in the plane of the meridian of the observatory. In either of those quadrants an index, which reaches from the centre to the edge of the arch, moves round that centre, or round a short axis which passes through that centre so as to be moveable with its extremity all round that arc, and thus point out on the divisions of the arch, the angle which it forms with the horizon, or with the vertical line, in any given situation. This index carries a telescope, through which the observer looks at any particular object, whose altitude he wishes to determine.

Plate Observatory, &c. fig. 1. represents a simple construction of a small moveable quadrant, and fig. 2. represents a mural quadrant. Of the quadrant fig. 1. CEB is the arch divided into 90°, and generally subdivided into smaller divisions, such as half degrees, or third parts of each degree, &c. The centre of the arch is at A, and the whole is connected together by means of strong metallic bars, as is shewn between the letters ABC in the figure: in the centre A, a short axis is fixed perpendicular to the plane of the instrument, and to the upper part of this axis is fastened the index AD, which carries the telescope. This index generally has a small lateral projection, as at E, upon which the nonius or vernier is marked, by which means the minutes or smaller parts of each degree may be discerned. (See VERNIER.) The screw P, commonly called the tangent screw, with a nut that may be fastened to any part of the arch BC, screws likewise into the extremity of the index, and is useful for moving the index gently, or more accurately than by the immediate application of the hand to the index itself.

Since the index is suspended at one end, viz. at A, if the other end D happens to be disengaged from the screw P, the lower end D of the index will naturally come down to C, on account of its own weight, and that of the telescope. Now, in order to avoid this tendency downwards, an arm Y of brass or iron, is frequently affixed to the upper part of the index, which carries the leaden weight Z, sufficient to balance the weight of the index and telescope; so that by this means, even when disengaged from the screw P, the index will remain in any situation in which it may be left. The whole frame ABC is supported upon a strong vertical axis FS, the lower part of which turns into the pedestal OKm, and carries an index SX, which moves upon the divided horizontal circle O, fixed to the pedestal. This serves to fix the plane of the quadrant in any azimuth that may be required. The lower part of the pedestal has three claws, with a screw m in each; by which means the axis FS may be set truly perpendicular. The plummet AO, suspended at A, serves to shew when the edge AC of the instrument is truly perpendicular, or when the first division of the arch at C is exactly in the vertical which passes through the centre A of the quadrantal arc BC. The weight of the plummet generally moves in a glass of water, which is fixed upon the arm GR; the object of which is to check the vibrations of the pendulum; which otherwise would be easily moved by every breath of air, and would continue to move for a considerable time after. We do not mention the lenses or microscopes that are applied to read off the divisions at E and at X, or to see the coincidence of the plummet-line with a dot marked upon the arc at C, as matters that need no particular description.

In the eye-tube of the telescope AD, there are certain slender wires, placed in the focus of the eye-lens, and perpendicular to the axis of the telescope, which enable the observer to distinguish more accurately when an object, that is seen through the telescope, reaches the axis of the telescope, or, as it is more commonly called, the line of collimation, &c. Now when the stars or planets are observed at night, those wires in the eye-tube cannot be seen; therefore, to render them visible, an arm or wire is fixed occasionally at the end of the telescope, which arm holds a small piece of ivory or card c, set aslant to the axis of the telescope; for when a lighted candle or lantern is situated at a little distance, and is directed so as to shine upon the above-mentioned ivory or card, the reflection of the light from it into the tube of the telescope will enable the observer to distinguish the wires at the same time that he beholds the celestial object.

The mural quadrant, fig. 2, is a larger instrument like the above, excepting that it has no stand; and its index is prevented from bending on account of its great length, by means of metallic bars, *d, f, b. c.* This instrument is firmly fixed upon a wall exactly in the plane of the meridian of the observatory, for which purpose it has clamps, screws, and other adjustments. It has likewise a plummet.

This undoubtedly is the principal instrument of an observatory; for by observing the times by the clock, of the arrival of any celestial object to the meridian, the right ascension of that object is had immediately; and its declination is shewn at the same time by the index of the quadrant upon the divided arch; deducting the inclination of the equator, which is given by the latitude once ascertained of the observatory. It is by this means that exact catalogues of the places of the fixed stars have been made.

The transit instrument consists of a telescope of any convenient length, fixed at right angles to a horizontal axis, which axis is supported at its two extremities; and the instrument is generally situated so that the line of collimation of the telescope may move in the plane of the meridian. The use of this instrument is to observe the precise time of the celestial bodies' passage across the meridian of the observatory.

Fig. 3. exhibits a transit instrument. N M is the telescope; in the eye-tube of which a system of parallel wires, is situated in the focus of the eye-lens. FE is the horizontal axis, in the middle of which the telescope is steadily fixed: so that by moving the telescope, the axis is forced to turn round its two extremities E and F, which rest in the notches of two thick pieces, T, S, of bell-metal, such as are delineated separately and magnified at X and Z. Those pieces are generally fixed upon two pillars, either of cast iron, or which is better, of stone, as are shewn in the figure; and they are constructed so as to be susceptible of a small motion by means of slides and screws, viz. the piece T backwards and forwards, and the piece S upwards and downwards; by which means the axis EF of the instrument may be set exactly horizontal, and caused to move perpendicular to the plane of the meridian. In order to verify the first of those requisites, viz. to see whether the axis is truly horizontal, the long spirit-level P Q is suspended upon it by means of the metallic branches PO and QR; and the situation of the bubble in it will immediately shew whether the axis is truly horizontal, or which way it inclines, and of course where it must be raised or depressed. The other requisite, viz. whether the axis is perpendicular to the plane of the meridian, or not, may be verified by various means, the best of which is by observations on those circumpolar stars which never go below the horizon of the observatory. Thus, observe the times by the clock, when a circumpolar star, seen through the telescope NM, crosses the meridian both above and below the pole; and if the times of describing the eastern and western parts of its circuit are equal, the telescope is then in the plane of the meridian, consequently the axis EF is perpendicular to that plane; otherwise the notched pieces T and S, which support the extremities E, F, of the axis, must be moved accordingly, or until upon observation it is found that the above-mentioned times of the stars' semi-revolutions are equal.

When the instrument has been once so adjusted, a mark may be made upon a house, or rock, or post, at some distance from the observatory, so that when viewed through the telescope, this mark may appear to be in the direction of the axis of the telescope; by which means the correct situation of the instrument may afterwards be readily verified.

The cylindric extremity F is perforated, and the perforation passes through the half of the axis, and reaches the inside of the telescope; that side of the telescope tube which is exactly facing F, being also perforated. Within the said tube, and directly opposite to the perforation of the end F, a plane reflector, or a flat piece of ivory, is fixed, making an angle of 45° with the axis of the telescope, and having a hole through it large enough to admit all the rays passing from the object-glass to the eye-glass of the telescope.

When stars or other celestial objects are to be observed in the night-time, a small lantern Y is set upon a stand just before the perforation of the extremity F, so as to throw the light within the axis, and upon the slant reflector within the tube of the telescope, whence it is reflected upon the wires in the eye-tube M, and renders them visible. By placing the lantern nearer to, or farther from, the extremity F, the observer may illuminate the wires sufficiently for the purpose, and not too much.

To the other extremity E of the axis, a divided circle, or sometimes a semicircle, is fixed, which turns with the axis; the index being fixed to the pillar which supports the axis. Sometimes the situation of those parts is reversed, viz. the circle is fastened to the pillar, or to the brass piece which supports the axis, and the index is fastened to the extremity E of the axis. The use of this circle, is to place the telescope in the direction of any particular celestial body, when that body crosses the meridian; which inclination is equal to the collatitude of the place, more or less the declination of the celestial body, according as that declination is north or south.

To adjust the clock by the sun's transit over the meridian.—Note the times by the clock when the preceding and following edges of the sun's limb touch the cross wires. The difference between the middle time and 12 hours, shews how much the mean, or time by the clock, is faster or slower than the apparent, or solar time, for that day; to which the equation of time being applied, will show the time of mean noon for that day, by which the clock may be adjusted.

Astronomical or equatorial sector, an instrument for finding the difference in right ascension and declination between two objects, the distance of which is too great to be observed by the micrometer, was invented by Graham. Let AB (fig. 4.) represent an arch of a circle, containing 10 or 12 degrees well divided, having a strong plate CD for its radius, fixed to the middle of the arch at D: let this radius be applied to the side of an axis HFI, and be moveable about a joint fixed to it at F, so that the plane of the sector may be always parallel to the axis HI; which being parallel to the axis of the earth, the plane of the sector will always be parallel to the plane of some hour-circle. Let a telescope CE be moveable about the centre C of the arch AB, from one end of it to the other, by turning a screw at G; and let the line of sight be parallel to the plane of the sector. Now, by turning the whole instrument about the axis HI, till the plane of it is successively directed, first to one of the stars and then to another, it is easy to move the sector about the joint F, into such a position, that the arch AB, when fixed, shall take in both the stars in their passage, by the plane of it, provided the difference of their declinations does not exceed the arch AB. Then, having fixed the plane of the sector a little to the westward of both the stars, move the telescope CE by the screw G; and observe by a clock the time of each transit over the cross hairs, and also the degrees and minutes upon the arch AB cut by the index at each transit; then in the difference of the arches, the difference of the declinations, and by the difference of the times, we have the difference of the right ascensions of the stars.

The dimensions of this instrument are these: The length of the telescope, or the radius of the sector, is $2\frac{1}{2}$ feet; the breadth of the radius, near the end C, is $1\frac{1}{4}$ inch; and at the end D two inches. The breadth of the limb AB is $1\frac{1}{2}$ inch; and its length six inches, containing ten degrees divided into quarters, and numbered from each end to the other. The telescope carries a nonius or subdividing plate, whose length, being equal to sixteen quarters of a degree, is divided into fifteen equal parts; which, in effect, divides the limb into minutes, and, by estimation, into smaller parts. The length of the square axis HFI is eighteen inches, and its thickness is about a quarter of an inch: the diameters of the circles are each 5 inches; the thickness of the plates, and the other measures, may be taken at the direction of a workman.

This instrument may be rectified, for making observations, in this manner: By placing the intersection of the cross hairs at the same distance from the plane of the sector, as the centre of the object-glass, the plane described by the line of sight during the circular motion of the telescope upon the limb will be sufficiently true, or free from conical curvity: which may be examined by suspending a long plumb-line at a convenient distance from the instrument; and by fixing the plane of the sector in a vertical position, and then by observing, while the telescope is moved by the screw along the limb, whether the cross hairs appear to move along the plumb-line.

The axis *h f o* (see figure below) may be elevated nearly parellel to the axis of the earth, by means of a small common quadrant; and its error may be corrected by making the line of sight follow the circular motion of any of the circumpolar stars, while the whole instrument is moved about its axis *hfo*, the telescope being fixed to the limb: for this purpose, let the telescope *k l* be directed to the star *a*, when it passes over the highest point of its diurnal circle, and let the division cut by the nonius be then noted: then after twelve hours, when the star comes to the lowest point of its circle, having turned the instrument half-round its axis to bring the telescope into the position *m n*; if the cross hairs cover the same star supposed at *b*, the elevation of the axis *hfo* is exactly right; but if it is necessary to move the telescope into the position *u v*, in order to point to this star at *c*, the arch *m u*, which measures the angle *mfu* or *bfc*, will be known; and then the axis *hfo* must be depressed half the quantity of this given angle if the star passed below *b*, or must be raised so much higher if above it; and thus the trial must be repeated till the true elevation of the axis is obtained. By making the like observations upon the same star on each side the pole, in the six o'clock hour-circle, the error of the axis, towards the east or west, may also be found and corrected, till the cross-hairs follow the star quite round the pole: for supposing *a o p b c* to be an arch of the meridian, make the angle *a f p* equal to half the angle *a f c*, and the line *fp* will point to the pole; and the angle *ofp*, which is the error of the axis, will be equal to half the angle *bfc*, or *mfu*, found by the observation; because the difference of the two angles *afb*, *afc*, is double the difference of their halves *afo* and *afp*. Unless the star is very near the pole, allowance must be made for refractions.

Equatorial or portable observatory: an instrument designed to answer a number of useful purposes in practical astronomy, independantly of any particular observatory; it may be made use of in any steady room or and performs most of the useful problems in the science.

The principal parts of this instrument (fig. 5.) are, 1. The azimuth or horizontal circle A, which represents the horizon of the place, and moves on an axis B, called the vertical axis. 2. The equatorial or hour circle C, representing the equator, placed at right angles to the polar axis D, or the axis of the earth, upon which it moves. 3. The semicircle of declination E, on which the telescope is placed, and moving on the axis of declination, or the axis of motion of the line of collimation F. These circles are measured and divided as in the following table:

Measures of the several circles, and divisions on them.	Radius in dec.	Limb divided to	Nonius of 30 gives seconds.	Divided on limb into parts of inc.	Divided by nonius into parts of inc.
Azimuth, or horizontal circle -	5 1	15′	30″	45th	1350th
Equatorial, or hour circle -	5 1	15′ } 1′ in time }	30″ } 2″ }	45th	1350th
Vertical semi-circle, for declination or latitude -	5 5	15′	30″.	45th	1260th

4. The telescope in this equatorial may be brought parallel to the polar axis, as in the figure, so as to point to the pole-star in any part of its diurnal revolution; and thus it has been observed near noon, when the sun has shone very bright. 5. The apparatus for correcting the error in altitude occasioned by refraction, which is applied to the eye-end of the telescope, and consists of a slide G moving in a groove or dovetail, and carrying the several eye-tubes of the telescope, on which slide there is an index corresponding to 5 small divisions engraved on the dovetail; a small circle called the refraction circle, H, moveable by a finger-screw at the extremity of the eye-end of the telescope; which circle is divided into half-minutes, one entire revolution of it being equal to 3′ 18″, and by its motion raises the centre of the cross hairs on a circle of altitude; and likewise a quadrant I of an inch and a half radius, with divisions on each side, one expressing the degree of altitude of the object viewed, and the other expressing the minutes and seconds of error occasioned by refraction, corresponding to that degree of altitude: to this quadrant is joined a small round level K, which is adjusted partly by the pinion that turns the whole of this apparatus, and partly by the index of the quadrant; for which purpose the refraction-circle is set to the same minute, &c. which the index points to on the limb of the quadrant; and if the minute, &c. given by the quadrant exceeds the 3′ 18″ contained in one entire revolution of the refraction-circle, this must be set to the excess above one or more of its entire revolutions; then the centre of the cross hairs will appear to be raised on a circle of altitude to the additional height which the error of refraction will occasion at that altitude.

The principal adjustment in this instrument is that of making the line of collimation to describe a portion of an hour-circle in the heavens; in order to which, the azimuth-circle must be truly level; the line of collimation, or some corresponding line represented by the small brass rod M parallel to it, must be perpendicular to the axis of its own proper motion; and this last axis must be perpendicular to the polar axis. On the brass rod M there is occasionally placed a hanging level N, the use of which will appear in the following adjustments.

The azimuth-circle may be made level by turning the instrument till one of the levels is parallel to an imaginary line joining two of the feet-screws; then adjust that level with these two feet-screws; turn the circle half round, that is, 180°; and if the bubble is not then right, correct half the error by the screw belonging to the level, and the other half error by the two feet-screws; repeat this till the bubble comes right; then turn the circle 90° from the two former positions, and set the bubble right, if it is wrong, by the foot-screw at the end of the level; when this is done, adjust the other level by its own screw, and the azimuth-circle will be truly level. The hanging level must then be fixed to the brass rod by two hooks of equal length, and made truly parallel to it: for this purpose make the polar axis perpendicular or nearly perpendicular to the horizon; then adjust the level by the pinion of the declination-semicircle, reverse the level, and if it is wrong, correct half the error by a small steel screw that lies under one end of the level, and the other half error by the pinion of the declination-semicircle; repeat this till the bubble is right in both positions. In order to make the brass rod on which the level is suspended, at right angles to the axis of motion of the telescope or line of collimation, make the polar axis horizontal, or nearly so; set the declination-semicircle to 0°, turn the hour-circle till the bubble comes right; then turn the declination-circle to 90°; adjust the bubble by raising or depressing the polar axis (first by hand till it is nearly right, afterwards tighten with an ivory-key the socket which runs on the arch with the polar axis, and then apply the same ivory key to the adjusting screw at the end of the said arch till the bubble comes quite right); then turn the declination-circle to the opposite 90°; if the level is not then right, correct half the error by the aforesaid adjusting screw at the end of the arch, and the other half error by the 2 screws which raise or depress the end of the brass rod. The polar axis remaining nearly horizontal as before, and the declination-semicircle at 0°, adjust the bubble by the hour-circle; then turn the declination-semicircle to 90°, and adjust the bubble by raising or depressing the polar axis; then turn the hour-circle 12 hours; and if the bubble is wrong, correct half the error by the polar axis, and the other half-error by the two pair of capstan-screws at the feet of the two supports on one side of the axis of motion of the telescope; and thus this axis will be at right angles to the polar axis. The next adjustment is to make the centre of cross hairs remain on the same object, while you turn the eye-tube quite round by the pinion of the refraction apparatus: for this adjustment, set the index on the slide to the first division of the dovetail; and set the division marked 18″ on the refraction-circle to its index; then look through the telescope, and with the pinion turn the eye-tube quite round; and if the centre of the hairs does not remain on the same spot during that revolution, it must be corrected by the four small screws, two and two at a time (which you will find upon unscrewing the nearest end of the eye-tube that contains the first eye-glass); repeat this correction till the centre of the hairs remains on the spot you are looking at during an entire revolution. In order to make the line of collimation parallel to the brass rod on which the level hangs, set the polar axis horizontal, and the declination-circle to 90°; adjust the level by the polar axis; look through the telescope on some distant horizontal object, covered by the centre of the cross hairs; then invert the telescope, which is done by turning the hour circle half-round; and if the centre of the cross hairs does not cover the same object as before, correct half the error by the uppermost and lowermost of the four small screws at the eye-end of the large tube of the telescope: this correction will give a second object now covered by the centre of the hairs, which must be adopted instead of the first object: then invert the telescope as before; and if the second object is not covered by the centre of the hairs, correct half the error by the same two screws which were used before: this correction will give a third object, now covered by the centre of the hairs, which must be adopted instead of the second object; repeat this operation till no error remains; then set the hour-circle exactly to 12 hours (the declination-circle remaining at 90° degrees as before); and if the centre of the cross hairs does not cover the last object fixed on, set it to that object by the two remaining small screws at the eye-end of the large tube, and then the line of collimation will be parallel to the brass rod. For rectifying the nonius of the declination and equatorial circles, lower the telescope as many degrees, minutes, and seconds, below 0° or Æ on the declination-semicircle, as are equal to the complement of the latitude; then elevate the polar axis till the bubble is horizontal, and thus the equatorial circle will be elevated to the co-latitude of the place; set this circle to 6 hours; adjust the level by the pinion of the declination-circle; then turn the equatorial circle exactly 12 hours from the last position; and if the level is not right, correct one half of the error by the equatorial circle, and the other half by the declination-circle; then turn the equatorial circle back again exactly 12 hours from the last position; and if the level is still wrong, repeat the correction as before till it is right when turned to either position; that being done, set the nonius of the equatorial circle exactly to 6 hours, and the nonius of the declination circle exactly to 0°.

The principal uses of this equatorial are,

1. To find the meridian by one observation only: for this purpose elevate the equatorial circle to the co-latitude of the place, and set the declination-semicircle to the sun's declination for the day and hour of the day required; then move the azimuth and hour circles both at the same time, either in the same or contrary directions, till you bring the centre of the cross hairs in the telescope exactly to cover the centre of the sun; when that is done, the index of the hour-circle will give the apparent or solar time at the instant of observation; and thus the time is gained, though the sun is at a distance from the meridian; then turn the hour-circle till the index points precisely at 12 o'clock, and lower the telescope to the horizon, in order to observe some point there in the centre of your glass, and that point is your meridian mark found by one observation only; the best time for this operation is three hours before or three hours after 12 at noon.

2. To point the telescope on a star, though not on the meridian, in full day-light. Having elevated the equatorial circle to the co-latitude of the place, and set the declination-semicircle to the star's declination, move the index of the hour-circle till it shall point to the precise time at which the star is then distant from the meridian, found in tables of the right ascension of the stars, and the star will then appear in the glass. Besides these uses peculiar to this instrument, it is also applicable to all the purposes to which the principal astronomical instruments, viz. a transit, a quadrant, and an equal-altitude instrument, are applied.

Of all the different sorts of chronometers or timekeepers, a pendulum-clock, when properly constructed, is undoubtedly capable of the greatest accuracy, it being liable to fewer causes of obstruction or irregularity; therefore such machines are most recommendable for an observatory. The situation of this clock must be near the quadrant, and near the transit instrument; so that the observer, whilst looking through the telescope of any of those instruments, may hear the beats of the clock and count the seconds.

We need hardly observe with respect to telescopes, that they are of very great use in an observatory. Indeed a telescope for the same can never be too good or too large; and it should be furnished with micrometers, with different eye-pieces, &c.; but as a large instrument of that sort is not easily managed, nor is always required, so there should be two or three telescopes of different sizes and different powers in every observatory. One at least ought to be fixed upon an axis which may move parallel to the axis of the earth; for in this construction the celestial bodies may, with the telescope, be easily followed in their movements; as the hand of the observer is, in that case, obliged to move the telescope in one direction only.

A pretty good telescope placed truly vertical in an observatory, is likewise a very useful instrument; as the aberration of the stars, latitude of the place, &c. may be observed and determined by the use of such an instrument, with great ease and accuracy.

The night telescope is a short telescope, which magnifies very little; but it collects a considerable quantity of light, and has a very great field of view; it therefore renders visible several dim objects, which cannot be discovered with telescopes of considerably greater magnifying powers; and hence it is very useful for finding out nebulæ, or small comets, or to see the arrangement of a great number of stars in one view.

The principal instruments that are at present used for marine astronomy, or for the purposes of navigation, are that incomparably useful instrument called Hadley's sextant, or quadrant, or octant; a portable chronometer; and a pretty good telescope. With these few instruments, the latitudes, longitudes, hours of the day or night, and several other problems useful to navigators, may be accurately solved. See OPTICS, and QUADRANT.

OBSIDIAN, in mineralogy, called also the Iceland agate, is found either in detached masses, or forming a part of rocks. It has the appearance of black glass. It is usually invested with a grey or opaque crust. Its fracture is conchoidal. Specific gravity 2.35 nearly. Colour black, or greyish-black; when in very thin pieces green. Very brittle. It melts into an opaque grey mass. It is composed of

69	silica
22	alumina
9	iron
100.	

OBTURATOR. See ANATOMY.

OCCIPITALES. See ANATOMY.

OCCULT, in geometry, is used for a line that is scarcely perceptible, drawn with the point of the compasses, or a leaden pencil. These lines are used in several operations, as the raising of plans, designs of buildings, pieces of perspective, &c. They are to be effaced when the work is finished.

OCCULTATION, *circle of perpetual*, is a parallel in an oblique sphere, as far distant from the depressed pole, as the elevated pole is from the horizon. All the stars between this parallel and the depressed pole, never rise, but lie constantly hid under the horizon of the place.

OCCUPATION, or OCCUPANCY. The law of occupancy is founded upon the law of nature, and is simply the taking possession of those things, which before belonged to nobody; and this is the true ground and foundation of all property. In the civil law it denotes the possession of such things as at present properly belong to no private person, but are capable of being made so; as by seizing or taking of spoils in war, by catching things wild by nature, as birds and beasts of game, &c. or by finding things before undiscovered, or lost by their proper owners.

OCCUPIERS *of walling*, a term in the salt-works for the persons who are the sworn officers that allot, in particular places, what quantity of salt is to be made, that the markets may not be overstocked, and see that all is carried fairly and equally between the lord and the tenant.

OCEAN, in geography, that vast collection of salt and navigable waters, in which the two continents, the first including Europe, Asia, and Africa, and the last America, are inclosed like islands. The ocean is distinguished into three grand divisions: 1. The Atlantic ocean, which divides Europe and Africa from America, which is generally about three thousand miles wide; 2. The Pacific ocean, or South-sea, which divides America from Asia, and is generally about ten thousand miles over; and, 3. The Indian ocean, which separates the East Indies from Africa, which is three thousand miles over. The other seas which are called oceans, are only parts or branches of these, and usually receive their names from the countries they border upon.

OCHNA, a genus of the monogynia order, in the polyandria class of plants; and in the natural method ranking with those of which the order is doubtful. The corolla is pentapetalous; the calyx pentaphyllous; the berries monospermous, and affixed to a large roundish receptacle. There are three species, trees of the East Indies and South America.

OCHRE, in natural history, a genus of earths, slightly coherent, and composed of fine, smooth, soft, argillaceous particles, rough to the touch, and readily diffusible in water. It is a combination of alumina and red oxide of iron. Ochres are of various colours, as red, blue, yellow, brown, green, &c.

OCHROMA, a genus of the pentandria order, in the monadelphia class of plants; and in the natural method ranking under the 37th order, columniferæ. The corolla consists of six petals, three of which are external, and the other three internal; the antheræ unite, and form a spiral pillar round the style; the capsule is long, and has five loculaments, which contain a number of black round seeds. Of this there is only one species, viz. the ochroma lagopus, the down-tree, or cork-wood. This tree is frequent in Jamaica, is of speedy growth, and rises to about 25 or 30 feet. The flowers are large and yellow. The capsules are about five inches long, rounded, and covered with a thin skin; which when dry falls off in five longitudinal segments, and leaves the fruit greatly resembling a hare's foot. The down is short, soft, and silky; it is used sometimes to stuff beds and pillows; but, like other vegetable downs, is apt to get into clots: an insipid clear gum exudes from the tree when wounded. The bark is tough, and its fibres are in a reticulated form; it might be made into ropes. The dried wood is so very light and buoyant, as to be used by the fishermen in Jamaica for their nets instead of pieces of cork.

OCHROXYLUM, a genus of the class and order pentandria trigynia. The calyx is five-cleft; petals five; nect. angular, three-lobed, gland.; capsules three, approximately, one-celled, two-seeded.

OCIMUM, or Ocymum, basil, a genus of the didynamia gymnospermia class of plants, with a bilabiated cup; its flower is monopetalous and ringent; and its seeds, which are four in number, are contained in the cup, which closes for that purpose. There are 25 species. Both the herbs and seed of basil are used in medicine, and are said to be good in disorders of the lungs, and to promote the menses.

OCTAGON, or Octogon, in geometry, is a figure of eight sides and angles; and this, when all the sides and angles are equal, is called a regular octagon, or one which may be inscribed in a circle. If the radius of a circle circumscribing a regular octagon is $= r$, and the side of the octagon $= y$; then $y = \sqrt{2r^2 - r\sqrt{2r^2}}$.

Octagon, in fortification, denotes a place that has eight bastions.

OCTAHEDRON, or Octaedron, in geometry, one of the five regular bodies, consisting of eight equal and equilateral triangles. The square of the side of the octahedron is to the square of the diameter of the circumscribing sphere, as 1 to 2. If the diameter of the sphere is 2, the solidity of the octahedron inscribed in it will be 1,33333 nearly. The octahedron is two pyramids put together at their bases; therefore its solidity may be found by multiplying the quadrangular base of either of them, by one third of the perpendicular height of one of them, and then doubling the product.

OCTANDRIA, the eighth class in Linnæus's sexual system; consisting of plants with hermaphrodite flowers, which are furnished with eight stamina, or male organs of generation. See Botany.

OCTANT, or Octile, in astronomy, that aspect of two planets, wherein they are distant an eighth part of a circle, or 45°, from each other.

OCTAVE, in music, an interval containing seven degrees, or twelve semitones, and which is the first of the consonances in the order of generation. The most simple perception that we can have of two sounds is that of unisons, which, resulting from equal vibrations, are as one to one; the next to this in simplicity is the octave, which is in double computation as one to two. The harmonies of these sounds have a perfect agreement, which distinguishes them from any other interval, and contributes to give them that unisonous effect which induces the common ear to confound them, and take them indifferently one for the other. This interval is called an octave, because moving diatonically from one term to the other, we produce eight different sounds. The octave comprehends all the primitive and original sounds; so that having established a system, or series of sounds, in the extent of an octave, we can only prolong that series by repeating the same order in a second octave, and again in a third, and so on, in all which we shall not find any sound that is not the replicate of some sound in the adjoining octave.

The complete and rigorous system of the octave requires three major tones, two minor, and two major semitones. The temperated system is of five equal tones, and two semitones, forming together seven diatonic degrees.

ODE. See Poetry.

ODONTOGNATHUS, a genus of fishes of the order apodes. The generic character is, mouth furnished with a strong moveable lamina or process on each side the upper jaw; gill-membrane five-rayed.

Aculeated odontognathus. The genus odontognathus consists of a single species, of which the following is the description. The head, body, and tail, are very compressed; the lower jaw, which is longer than the upper, is very much elevated towards the other when the mouth is closed, insomuch as to appear almost vertical; and is lowered somewhat in the manner of a drawbridge when the mouth is opened, when it appears like a small scaly boat, very transparent, furrowed beneath, and finely denticulated on the margins; this lower jaw, in the act of depression, draws forwards two flat, irregular laminæ, of a scaly substance, a little bent at their posterior end, and larger at their origin than at their tips, denticulated on their anterior margin, and attached, one on one side and the other on the opposite, to the most prominent part of the upper jaw; when the mouth is closed again, these pieces apply themselves on each side to one of the opercula, of which they represent the exterior denticulated border; in the middle of these jaws is placed the tongue, which is pointed and free in its movements; the gill-covers, which are composed of several pieces, are very transparent at the hind part, but scaly and of a bright silver-colour in front; the gill-membrane is also silvery, and has five rays; the breast is terminated below by a sharp carina furnished with eight crooked spines; the carina of the belly is also furnished with twenty-eight spines, disposed in two longitudinal ranges; the anal fin is very long, and extends almost as far as the base of the tail-fin, which is of a forked shape; the dorsal fin is placed on the tail, properly speaking, at about three quarters of the whole length of the animal, but it is extremely small. The general length of this fish is three decimetres, and its colour, so far as may be conjectured from specimens preserved for some time in spirits, is a bright silver. It is a native of the American seas, and is common about the coasts of Cayenne, where it ranks in the number of edible fishes.

OECONOMY, *animal*, comprehends the various operations of nature, in the generation, nutrition, and preservation of animals. See Anatomy, Physiology, Comparative Anatomy, Digestion, &c.

OEDEMA. See Surgery.

OEDERA, a genus of the syngenesia polygamia-segregata class and order; the calyx many-flowered; corollets tubular, hermaphrodite, with one or two female ligulate florets: recep. chaffy, down of several chaffs. There are two species, herbs of the Cape.

OENANTHE, water (or hemlock) dropwort: a genus of the digynia order, in the pentandria class of plants; and in the natural method ranking under the 45th order, umbellatæ. The florets are difform; those of the disc sessile and barren; the fruit crowned with the calyx. There are 11 species, of which the most remarkable is the crocata, or hemlock dropwort, growing frequently on the banks of ditches, rivers, and lakes, in many parts of Britain. The root and leaves of this plant are a strong poison; several persons have perished by eating it through mistake, either for water-parsnips or for celery, which last it much resembles in its leaves. So exceedingly deleterious is this plant, that Mr. Lightfoot tells us he has heard the late Mr. Christopher d'Ehret, the celebrated botanic painter say, that while he was drawing it, the smell or effluvia rendered him so giddy, that he was several times obliged to quit the room, and walk out in the fresh air to recover himself; but recollecting at last what might be the probable cause of his repeated illness, he opened the door and windows of the room, and the free air then enabled him to finish his work without any more returns of the giddiness. Mr. Lightfoot informs us, that he has given a spoonful of the juice of this plant to a dog, but without any other effect than that of making him very sick and stupid. In about an hour he recovered; and our author has seen a goat eat it with impunity. To such of the human species as have unfortunately eaten any part of this plant, a vomit is the best remedy.

Lobel, Ray, and others, call this vegetable œnanthe aquatica cicutæ facie. It grows in great plenty all over Pembrokeshire, and is called by the inhabitants five-fingered root; it is much used by them in cataplasms for the felon or worst kind of whitlow. They eat some parts of it, but carefully avoid the roots or stalk. These indeed are of a most pernicious nature, and never fail to prove instantly fatal unless a proper remedy is applied.

OENOTHERA, TREE-PRIMROSE: a genus of the monogynia order, in the octandria class of plants; and in the natural method ranking under the 17th order, calycanthemæ. The calyx is quadrifid; the petals four; the capsule cylindric beneath; the seeds naked. There are 11 species; the most remarkable of which are: 1. The biennis, or common biennial tree-primrose, with large bright-yellow flowers. 2. Octovalvis, or octovalved, smooth, biennial tree-primrose, with large bright-yellow flowers. 3. The fruticosa, or shrubby narrow-leaved perennial tree-primrose, with clusters of yellow flowers, succeeded by pedicellated, acute-angled capsules. 4. The pumila, or low perennial tree-primrose, with bright-yellow flowers, succeeded by acute-angled capsules.

These plants are exotics from America; but are all very hardy, prosper in any common soil and situation, and have been long in the English gardens, especially the three first sorts; but the oenothera biennis is the most commonly known.

OESOPHAGUS. See ANATOMY.

OESTRUS, a genus of insects of the order diptera: the generic character is, antennæ triarticulate, very short, sunk; face broad, depressed, vesicular; mouth, a simple orifice; feelers two, biarticulate, sunk; tail inflected. The genus oestrus or gad-fly is remarkable, like that of ichneumon, for the singular residence of its larvæ; viz. beneath the skin, or in different parts of the bodies of quadrupeds.

The principal European species is the oestrus bovis, or ox-gadfly. This is about the size of a common bee, and is of a pale yellowish-brown colour, with the thorax marked by four longitudinal dusky streaks, and the abdomen by a black bar across the middle, the tip being covered with tawny or orange-coloured hairs; the wings are pale brown, and unspotted.

The female of this species, when ready to deposit her eggs, fastens on the back of a heifer or cow, and piercing the skin with the tube situated at the tip of the abdomen, deposits an egg in the puncture; she then proceeds to another spot at some distance from the former, repeating the same operation at intervals on many parts of the animal's back. This operation is not performed without severe pain to the animal on which it is practised; and it is for this reason that cattle are observed to be seized with such violent horror when apprehensive of the approaches of the female oestrus; flying with uncontrolable rapidity, and endeavouring to escape their tormentor by taking refuge in the nearest pond; it being observed that this insect rarely attacks cattle when standing in water.

In the punctures of the skin thus formed by the gadfly, the several eggs hatch; and the larvæ, by their motion and suction, cause so many small swellings or abscesses beneath the skin, which growing gradually larger, become externally visible, exhibiting so many tubercles an inch or more in diameter, with an opening at the top of each, through which may be observed the larva, imbedded in a purulent fluid; its appearance is that of an oval maggot of a yellowish-white colour while young, but growing gradually darker as it advances in age, till at the time of its full growth it is entirely brown. It is chiefly in the months of August and September that the eggs are laid, and the larvæ remain through the ensuing winter, and till the latter part of the next June, before they are ready to undergo their change into chrysalis. At this period they force themselves out from their respective cells, and falling to the ground, each creeps beneath the first convenient shelter, and lying in an inert state becomes contracted into an oval form, but without casting the larva skin, which dries and hardens round it. When the included insect is ready for exclusion, it forces open the top of the pupa or chrysalis coat, and emerges in its perfect form, having remained within the chrysalis somewhat more than a month.

Though the history of this insect in its larva state has long ago been detailed with sufficient accuracy by Vallisneri, Reaumur, and others, yet the fly itself appears to have been very generally confounded, and that even by Linnæus himself, with a very different species, resembling it in size, but which is bred in the stomach and intestines of horses, the larvæ being no other than the whitish rough maggots which farriers call by the title of bots. This insect is the oestrus equi; it is a trifle smaller than the oestrus bovis, and is of a yellowish-brown colour, with a dusky band across the thorax, and the tip of the abdomen of similar colour; the wings are whitish, with a pale dusky bar across the middle of each, and two dusky spots at the tip.

The manner in which the young larvæ or bots are introduced into the stomach and bowels of the animal they infest is singularly curious. When the female has been impregnated, and the eggs are sufficiently matured, she seeks among the horses a subject for her purpose, and approaching it on the wing, she holds her body nearly upright in the air, and her tail, which is lengthened for the purpose, curved inwards and upwards; in this way she approaches the part where she designs to deposit her egg; and suspending herself for a few seconds before it, suddenly darts upon it, and leaves her egg adhering to the hair; she hardly appears to settle, but merely touches the hair with the egg held out on the projected point of the abdomen. The egg is made to adhere by means of a glutinous liquor secreted with it. She then leaves the horse at a small distance, and prepares a second egg, and, poising herself before the part, deposits it in the same way. The liquor dries, and the egg becomes firmly glued to the hair; this is repeated by various flies till four or five hundred eggs are sometimes placed on one horse. The horses, when they become used to this fly, and find that it does them no injury (as the tabani and conopes, by sucking their blood), hardly regard it, and do not appear at all aware of its insidious object. The skin of the horse is always thrown into a tremulous motion on the touch of this insect; which merely arises from the very great irritability of the skin and cutaneous muscles at this season of the year, occasioned by the continual teasing of the flies, till at length these muscles act involuntarily on the slightest touch of any body whatever. The inside of the knee is the part on which these flies are most fond of depositing their eggs, and next to this on the side and back part of the shoulder, and less frequently on the extreme ends of the mane. But it is a fact worthy of attention, that the fly does not place them promiscuously about the body, but constantly on those parts which are most liable to be licked with the tongue: and the ova therefore are always scrupulously placed within its reach; for, when they have remained on the hairs four or five days, they become ripe, after which time the slightest application of warmth and moisture is sufficient to bring forth in an instant the latent larva. At this time, if the tongue of the horse touches the egg, its operculum is thrown open, and a small active worm is produced, which readily adheres to the moist surface of the tongue, and is thence conveyed with the food to the stomach.

These larvæ attach themselves to every part of the stomach, but are generally most numerous about the pylorus, and are sometimes, though much less frequently, found in the intestines. Their numbers in the stomach are very various, often not more than half a dozen, at other times more than a hundred, and if some accounts might be relied on, even a much greater number than this. They hang most commonly in clusters, being fixed by the small end to the inner membrane of the stomach, which they adhere to by means of two small hooks or tentacula. When they are removed from the stomach they will attach themselves to any loose membrane, and even to the skin of the hand.

The body of the larva is composed of eleven segments, all of which, except the two last, are surrounded with a double row of horny bristles directed towards the truncated end, and are of a reddish colour, except the points, which are black. These larvæ evidently receive their food at the small end, by a longitudinal aperture, which is situated between two hooks or tentacula. Their food is probably the chyle, which, being nearly pure aliment, may go wholly to the composition of their bodies without any excrementitious residue; though on dissection the intestine is found to contain a yellow or greenish matter, which is derived from the colour of the food, and shews that the chyle, as they receive it, is not perfectly pure.

They attain their full growth about the latter end of May, and are coming from the horse from this time to the latter end of June, or sometimes later. On dropping to the ground they find out some convenient retreat, and change to the chrysalis; and in about six or seven weeks the fly appears.

Oestrus ovis, or the sheep-gadfly, is so named from its larva inhabiting the nostrils and frontal sinuses of sheep in particular, though it is also found in similar situations in deer and some other quadrupeds. It is a smaller species than either of the two preceding, and is of a whitish-grey colour, with the thorax marked by four longitudinal black streaks, and the abdomen speckled with black. The larvæ are nearly as large as those of the oestrus equi, and, according to the observations of Mr. Clark, are of a delicate white colour, flat on the under side, and convex on the upper; having no spines at the divisions of the segments, though they are provided with tentacula at the small end. The other is truncated, with a prominent ring or margin. When young these larvæ are perfectly white and transparent; but as they increase in size the upper side becomes marked with two transverse brown lines on each segment, and some spots are seen on the sides. They move with considerable quickness, holding with their tentacula as a fixed point, and drawing up the body towards them. When full-grown they fall through the nostrils, and change to the pupa or chrysalis state, lying on the ground, or adhering to some blade of grass. The fly proceeds from the chrysalis in the space of about two months.

The other British oestri are the oestrus hæmorrhoidalis of Linnæus, whose larva, like that of the oestrus equi, resides in the stomachs of horses; and the oestrus veterinus of Mr. Clark, the larva of which is also found in similar situations. The oestrus hæmorrhoidalis is about the size of a common window-fly, with pale dusky wings, brown thorax, abdomen white at the base, black in the middle, and red at the tip. The oestrus veterinus is nearly of similar size with the oestrus equi, and is entirely of a ferruginous colour, with the abdomen more dusky towards the tip. The oestrus tarandi inhabits Lapland, and deposits its eggs on the back of the rein-deer, and is often fatal to them. See Plate Nat. Hist. fig. 299.

The other exotic oestri are probably numerous, but are at present very little known.

Whether the formidable African fly, described by Mr. Bruce under the name of zimb or tsaltsalya, may be referred to this genus or not, we shall not pretend to determine; there are however some particulars in its history which would lead one to suppose it an oestrus.

"This insect," says Mr. Bruce, "is a proof how fallacious it is to judge by appearances. If we consider its small size, its weakness, want of variety or beauty, nothing in the creation is more contemptible and insignificant. Yet passing from these to his history, and to the account of his powers, we must confess the very great injustice we do him from want of consideration. We are obliged, with the greatest surprise, to acknowledge, that those huge animals the elephant, the rhinoceros, the lion, and the tiger, inhabiting the same woods, are still vastly his inferiors; and that the appearance of this small insect, nay, his very sound, though he is not seen, occasions more trepidation, movement, and disorder, both in the human and brute creation, than would whole herds of these monstrous animals collected together, though their number was in a tenfold proportion greater than it really is.

"This insect is called zimb; it has not been described by any naturalist. It is in size very little larger than a bee, and his wings, which are broader than those of a bee, placed separate, like those of a fly. As soon as this plague appears, and their buzzing is heard, all the cattle forsake their food, and run wildly about the plain, till they die, worn out with fatigue, fright, and hunger. No remedy remains for the residents on such spots but to leave the black earth, and hasten down to the sands of Atbara, and there they remain while the rains last, this cruel enemy never daring to pursue them farther.

"What enables the shepherd to perform the long and toilsome journeys across Africa is the camel, emphatically called the ship of the desert. Though his size is immense, as is his strength, and his body covered with a thick skin, defended with strong hair, yet still he is not capable to sustain the violent punctures the fly makes with his proboscis. He must lose no time in removing to the sands of Atbara; for when once attacked by this fly, his body, head, and legs, break out into large bosses, which swell, break, and putrify, to the certain destruction of the creature. Even the elephant and rhinoceros, who, by reason of their enormous bulk, and the vast quantity of food and water they daily need, cannot shift to desert and dry places as the season may require, are obliged to roll themselves in mud and mire, which, when dry, coats them over like armour, and enables them to stand their ground against this winged assassin; yet I have found some of these tubercles upon almost every elephant and rhinoceros that I have seen, and attribute them to this cause." There are twelve species of this insect.

OFFENCE, is any act committed against any law. Offences are either capital or not capital. Capital offences are those for which an offender shall lose his life; not capital, where the offender may lose his lands and goods, be fined, or suffer corporal punishment, or both, but not loss of life. High treason, petit treason, and felony, constitute capital offences; other offences, not capital, include the remaining part of criminal offences or pleas of the crown, and come under the denomination of misdemeanors.

OFFERINGS. Oblations and offerings partake of the nature of tithes; and all persons which, by the laws of this realm, ought to pay their offerings, shall yearly pay to the parson, vicar, proprietary, or their deputies, or farmers of the parishes where they dwell, at such four offering days as heretofore within the space of four years last past have been accustomed; and in default thereof, shall pay for the said offerings at Easter following. 2 and 3 Ed. VI. c. 13.

OFFICE, is that function, by virtue whereof a person has some employment in the affairs of another. An office is a right to exercise any public or private employment, and to take the fees and emoluments thereunto belonging, whether public as those of magistrates, or private as of bailiffs, receivers, &c.

The statute 5 and 6 Edward VI. c. 16, declares all securities given for the sale of offices unlawful. And if any person shall bargain or sell, or take any reward, or promise of reward, for any office, or the deputation of any office, concerning the revenue, or the keepers of the king's castles, or the administration and execution of justice, unless it is such an office as had been usually granted by the justices of the king's bench or common pleas, or by justices of assize, every such person shall not only forfeit his right to such office, or to the nomination thereof, but the person giving such reward, &c. shall be disabled to hold such office. But it has been decided, that where an office is within the statute, and the salary certain, if the principal makes a deputy, reserving by bond a less sum out of the salary, it is good; or, if the profits are uncertain, reserving a part as half the profits, it is good; for the fees still belong to the principal, in whose name they must be sued for. Salk. 466. But where a person so appointed, gives a bond to the principal to pay him a sum certain, without reference to the profits; this is void under the statute. Salk. 465.

To offer money to any officer of state, to procure the reversion of an office in the gift of the crown, is a misdemeanor at common law, and punishable by information; and even the attempt to induce him under the influence of a bribe, is criminal, though never carried into execution. Any contract to procure the nomination to an office, not within the stat. 6 Ed. VI. is defective on the ground of public policy, and the money agreed to be given is not recoverable.

Office, in the canon-law, is used for a benefice that has no jurisdiction annexed to it. It is also used for divine service celebrated in public; and in the Romish church it is applied to a particular prayer preferred in honour of some saint; thus, when any saint is canonized, a particular office is at the same time assigned him, out of the common office of the confessors, the Virgin, &c. We say the office of the Holy Spirit, of the Virgin, of the passion, of the holy sacrament, of the dead, &c.

OFFICER, a person possessed of a post or office. See the preceding article. The great officers of the crown, or state, are the lord high steward, the lord high chancellor, the lord high treasurer, the lord president of the council, the lord privy seal, the lord chamberlain, the lord high constable, the earl marshal; each of which see under its proper article.

Officers, *commission*, are those appointed by the king's commission; such are all from the general to the cornet inclusive, who are thus denominated in contradistinction to warrant-officers, who are appointed by the colonel's or captain's warrant, as quarter-masters, serjeants, corporals, and even chaplains and surgeons.

Officers, *general*, are those whose command is not limited to a single company, troop, or regiment; but extends to a body of forces, composed of several regiments; such are the general, lieutenant general, major-generals, and brigadiers.

Officers, *staff*, are such as, in the king's presence, bear a white staff or wand; and at other times, on their going abroad, have it carried before them by a footman bare-headed; such are the lord steward, lord chamberlain, lord treasurer, &c.

The white staff is taken for a commission, and at the king's death each of these officers breaks his staff over the hearse made for the king's body, and by this means lays down his commission, and discharges all his inferior officers.

Officers, *subaltern*, are all who administer justice in the name of subjects; as those who act under the earl marshal, admiral, &c. In the army, the subaltern officers are the lieutenants, cornets, ensigns, serjeants, and corporals.

OFFICIAL, in the canon law, an ecclesiastical judge, apointed by a bishop, chapter, abbot, &c. with charge of the spiritual jurisdiction of the diocese. Of these there are two kinds; the one is in a manner the vicar-general of the diocese, and is called by the canonists officialis principalis, and in our statute-law, the bishop's chancellor. There is no appeal from his court to the bishop, his being esteemed the bishop's court. The other called officialis foraneus, and is appointed by the bishop when the diocese is very large; he has but a limited jurisdiction, and has a certain extent of territory assigned him, wherein he resides.

OFFING, or Offin, in the sea-language, that part of the sea a good distance from shore, where there is deep water, and no need of a pilot to conduct the ship; thus, if a ship from shore is seen sailing out to seaward, they say, she stands for the offing; and if a ship, having the shore near her, has another a good way without her, or towards the sea, they say, that ship is in the offing.

OIL, which is of such extensive utility in the arts, was known at a very remote period. It is mentioned in Genesis, and during the time of Abraham was even used in lamps. The olive was very early cultivated, and oil extracted from it in Egypt. Cecrops brought it from Sais, a town in Lower Egypt, where it had been cultivated from time immemorial, and taught the Athenians to extract oil from it. In this manner the use of oil became known in Europe. But the Greeks seem to have been ignorant of the method of procuring light by means of lamps till after the siege of Troy; at least Homer never mentions them, and constantly describes his heroes as lighted by torches of wood. There are two classes of oils exceedingly different from each other; namely, fixed oils and volatile oils.

Fixed oils are distinguished by the following characters:

1. Liquid, or easily becoming so when exposed to a gentle heat. 2. An unctuous feel. 3. Very combustible. 4. A mild taste. 5. Boiling point not under 600°. 6. Insoluble in water and alcohol. 7. Leave a greasy stain upon paper.

These oils which are called also fat or expressed oils, are numerous; and are obtained, partly from animals and partly from vegetables, by simple expression. As instances may be mentioned, whale-oil or train-oil obtained from the blubber of the whale; olive-oil, obtained from the fruit of the olive; linseed-oil and almond-oil, obtained from linseed and almond-kernels. Fixed oils may also be extracted from poppy-seeds, hempseeds, beech-mast, and many other vegetable substances.

It deserves attention, that the only part of vegetables in which fixed oils are found is the seeds of bicotyledinous plants. In animals they are most usually deposited in the liver, though they are found also in the eggs of fowls.

All these oils differ from each other in several particulars, but they also possess many particulars in common. Whether the oily principle in all the fixed oils is the same, and whether they owe their differences to accidental ingredients, is not yet completely ascertained, as no proper analysis has hitherto been made; but it is not improbable, as all the oils hitherto tried have been found to yield the same products. In the present state of our knowledge, it would be useless to give a particular description of all the fixed oils, as even the differences between them have not been accurately ascertained.

Fixed oils are considered at present as composed of hydrogen and carbon. Lavoisier analysed olive-oil by burning a given portion of it in oxygen gas, by means of a particular apparatus. During the combustion there was consumed

Of oil -	15.79 grains troy
Of oxygen gas	50.86
Total	66.65

The products were carbonic acid and water. The carbonic acid obtained amounted to 44.50 grains; the weight of the water could not be accurately ascertained; but as the whole of the substances consumed were converted into carbonic acid gas and water, it is evident, that if the weight of the carbonic acid is subtracted from the weight of these substances, there must remain precisely the weight of the water. Mr. Lavoisier accordingly concluded, by calculation, that the weight of the water was 22.15 grains. Now the quantity of oxygen in 44.50 grains of carbonic acid gas is 32.04 grains, and the oxygen in 22.15 grains of water is 18.82 grains; both of which taken together amount to 50.86 grains, precisely the weight of the oxygen gas employed.

The quantity of charcoal in 44.50 grains of carbonic acid gas is 12.47 grains; and the quantity of hydrogen in 22.15 grains of water is 3.32 grains; both of which, when taken together, amount to 15.79 grains, which is the weight of the oil consumed.

It follows, therefore, from this analysis, that 15.79 grains of olive oil are composed of

12.47 carbon
3.32 hydrogen.

Olive-oil therefore is composed of about

79 carbon
21 hydrogen

100.

This however can only be considered as a very imperfect approximation towards the truth.

Fixed oil is usually a liquid with a certain degree of viscidity, adhering to the sides of the glass vessels in which it is contained, and forming streaks. It is never perfectly transparent, having always a certain degree of colour; most usually it is yellowish or greenish. Its taste is sweet, or nearly insipid. When fresh, it has little or no smell. Its specific gravity varies from 0.9403 (the specific gravity of linseed-oil) to 0.9153 (the specific gravity of olive-oil).

Fixed oil is insoluble in water. When the two liquids are agitated together, the water loses its transparency, and acquires the white colour and consistency of milk. This mixture is known by the name of emulsion. When allowed to remain at rest, the oil soon separates, and swims upon the surface of the water.

Fixed oil does not evaporate till it is heated to about 600°. At that temperature it boils, and may be distilled over; but it is always somewhat altered by the process. Some water and sebacic acid seem to be formed, a little charcoal remains in the retort, and the oil obtained is lighter, more fluid, and has a stronger taste, than before. Oil thus distilled was formerly distinguished by the name of philosophical oil.

Fixed oil, when in the state of vapour, takes fire on the approach of an ignited body, and burns with a yellowish-white flame. It is upon this principle that candles and lamps burn. The tallow or oil is first converted into the state of vapour in the wick; it then takes fire, and supplies a sufficient quantity of heat to convert more oil into vapour; and this process goes on while any oil remains.

The wick is necessary to present a sufficiently small quantity of oil at once for the heat to act upon. If the heat was sufficiently great to keep the whole oil at the temperature of 600°, no wick would be necessary, as is obvious from oil catching fire spontaneously when it has been raised to that temperature.

When exposed to the action of cold, fixed oils lose their fluidity, and are converted into ice; but this change varies exceedingly in different oils.

When fixed oils are exposed to the open air or to oxygen gas, they undergo different changes according to the nature of the oil:

1. Some of them dry altogether, without losing their transparency, when thin layers of them are exposed to the atmosphere. These are distinguished by the name of drying oils, and are employed by painters. Linseed-oil, nut-oil, poppy-oil, and hempseed-oil, possess this property; but linseed-oil is almost the only one of these liquids employed in this country as a drying oil. The cause of this peculiarity has not been completely investigated; but it is well known that these oils possess the drying quality at first but imperfectly. Before they can be employed by painters, they must be boiled with a little litharge. During this operation the litharge is partly reduced to the metallic state. Hence it has been conjectured that drying oils owe their peculiar properties to the action of oxygen; which is supposed either to constitute one of their component parts, or to convert them into drying oils by diminishing their hydrogen.

2. Other fixed oils, when exposed to the atmosphere, gradually become thick, opaque, and white, and assume an appearance very much resembling wax or tallow. These have been distinguished by the term fat oils. Olive-oil, oil of sweet almonds, of rape-seed, and of ben, belong to this class.

When oil is poured upon water, so as to

form a thin layer on its surface, and is in that manner exposed to the atmosphere; these changes are produced much sooner. Berthollet, who first examined these phenomena with attention, ascribed them to the action of light: but Sennebier observed that no such change was produced on the oil though ever so long exposed to the light, provided atmospherical air was excluded; but that it took place on the admission of oxygen gas, whether the oil was exposed to the light or not. It cannot be doubted, then, that it is owing to the action of oxygen. It is supposed at present to be the consequence of the simple absorption of oxygen and its combination with the oils.

3. Both these classes of oils, when exposed in considerable quantity to the action of the atmosphere, undergo another change, well known under the name of rancidity. But the fat oils become rancid much more readily than the drying oils. Rancid oils are thick, have usually a brown colour, convert vegetable blues to red, and have the smell and taste of sebacic acid. During the change which they undergo, some drops of water also appear on their surface. The rancidity of oils then is owing to the formation of a quantity of acid in them. This, together with the water, is evidently the consequence of a partial decomposition.

Fixed oils readily dissolve sulphur when assisted by heat. The solution assumes a reddish colour. When distilled, there comes over a great quantity of sulphureted hydrogen gas. When the solution is allowed to cool, the sulphur is deposited in chrystals. By this process Pelletier obtained sulphur in regular octahedrons.

They likewise dissolve a small proportion of phosphorus when assisted by heat. These oily phosphurets emit the odour of phosphureted hydrogen, and yield, when distilled, a portion of that gas. When rubbed in the open air, or when spread upon the surface of other bodies, they appear luminous in consequence of the combustion of the phosphorus. When hot oils saturated with phosphorus are allowed to cool, the phosphorus chrystallizes in octahedrons, as Pelletier ascertained.

Charcoal has no sensible action on fixed oils; but when they are filtred through charcoal-powder, they are rendered purer, the charcoal retaining their impurities. Neither hydrogen nor azotic gas has any action on fixed oils.

Fixed oils have scarcely any action upon metals; but they combine with several metallic oxides, and form compounds known by the name of plasters. See Plaster.

They combine likewise with alkalies and earths, and form with them compounds called soaps. The fat oils enter into these combinations much more readily than the drying oils. See Soap.

Fixed oils absorb nitrous gas in considerable quantities, and at the same time become much thicker and specifically heavier than before.

Sulphuric acid decomposes fixed oils, at least when concentrated. It renders them first thick and of a brown colour; then water is formed, charcoal precipitated, and an acid formed. Nitric acid renders them thick and viscid. When nitrous acid is poured upon the drying oils, it inflames them without addition; but it does not produce that effect upon the fat oils, unless it is mixed with a portion of sulphuric acid.

The affinities of fixed oils are as follows:

Lime,	Ammonia,
Barytes,	Oxide of mercury,
Fixed alkalies,	Other metallic oxides,
Magnesia,	Alumina.

The importance of fixed oils is well known. Some of them are employed as seasoners of food; some are burnt in lamps; some form the basis of soap; not to mention their utility in painting, and the many other important purposes which they serve.

Oils, *volatile*, called also essential oils, are distinguished by the following properties:

1. Liquid; often almost as liquid as water; sometimes viscid.
2. Very combustible.
3. An acrid taste and a strong fragrant odour.
4. Boiling point not higher than 212°.
5. Soluble in alcohol; and imperfectly in water.
6. Evaporate without leaving any stain on paper.

By this last test it is easy to discover whether they have been adulterated with any of the fixed oils. Let a drop of the volatile oil fall upon a sheet of writing-paper, and then apply a gentle heat to it. If it evaporates without leaving any stain upon the paper, the oil is pure; but if it leaves a stain, it has been contaminated with some fixed oil or other.

Volatile oils are almost all obtained from vegetables, and they exist in every part of plants; the root, the bark, the wood, the leaves, the flower, and even the fruit: though they are never found in the substance of the cotyledons; whereas the fixed oils, on the contrary, are almost always contained in these bodies.

When the volatile oils are contained in great abundance in plants, they are sometimes obtained by simple expression. This is the case with the oil of oranges, of lemons, and of bergamot; but in general they can only be obtained by distillation. The part of the plant containing the oil is put into a still with a quantity of water, which is distilled off by the application of a moderate heat. The oil comes over along with the water, and swims upon its surface in the receiver. By this process are obtained the oils of peppermint, thyme, lavender, and a great many others, which are prepared and employed by the perfumer. Others are procured by the distillation of resinous bodies. This is the case in particular with oil of turpentine, which is obtained by distilling a kind of resinous juice, called turpentine, that exudes from the juniper.

The greater number of volatile oils are liquid, and some of them are as transparent and colourless as water. This is the case with the oil of turpentine; but for the most part they are coloured. Some of them are yellow, as the oil of lavender; some brown, as the oil of rhodium; some blue, as the oil of camomile; but the greater number of volatile oils are yellow or reddish-brown.

Their odours are so various as to defy all description. It is sufficient to say, that all the fragrance of the vegetable kingdom resides in the volatile oils. Their taste is always acrid, hot, and exceedingly unpleasant. Their specific gravity is for the most part less than that of water; but some volatile oils, as those of canella and sassafras, are heavier than water. The specific gravity of the volatile oils varies from 0.8697 to 1.0439.

Water dissolves a small portion of volatile oils, and acquires the odour and the taste of the oil which it holds in solution.

When heated, they evaporate very readily and without alteration. They are much more combustible than fixed oils, owing to their greater volatility. They burn with a fine bright white flame, exhale a great deal of smoke, deposit much soot, and consume a greater proportion of the oxygen of the atmosphere than fixed oils. The products of their combustion are water and carbonic acid gas. From these facts it has been concluded that they are composed of the same ingredients as the fixed oils, but that they contain a greater proportion of hydrogen.

When exposed to the action of cold they congeal like the fixed oils; but the temperature necessary to produce this effect, varies according to the oil. Some of them, as oil of anise and of fennel, become solid at the temperature of 50°; frozen oil of bergamot and of canella become liquid at 23°; oil of turpentine at 14°. Margueron exposed several volatile oils to a cold of 17°. They congealed or rather chrystallized partially, and at the same time emitted an elastic fluid. These chrystals consisted partly of the oils themselves, partly of other substances. Some of them had the properties of benzoic acid.

Volatile oils, when exposed to the action of light in close vessels, and excluded from common air, undergo very singular changes. Their colour becomes deeper, they acquire a great deal of consistency, and their specific gravity is considerably increased. The cause of these changes is but imperfectly known. Tingry, to whom we are indebted for these interesting researches, has proved that light is a necessary agent. It was supposed formerly that they were occasioned by the absorption of oxygen; and when oxygen is present, it has been ascertained that it is absorbed; but Tingry has proved that the same changes go on when oxygen is excluded. This philosopher ascribes them to the fixation of light. If this is the real cause, the quantity of light fixed must be enormous; for as the specific gravity of the oils is increased considerably while the bulk continues the same, it is evident that the absolute weight must be increased proportionably. One circumstance, however, renders this conclusion somewhat doubtful, at least in its full extent; and that is, that the quantity of change was always proportional to the quantity of the oil and the quantity of air contained in the vessel.

When exposed to the open air their colour becomes gradually deeper, and they acquire consistency, while they exhale at the same time a very strong odour. The air around, as Priestley first ascertained, is deprived of its oxygen, a quantity of water is formed, and the oils at last, for the most part, assume the form of resins.

Volatile oils dissolve sulphur and phosphorus, and the solutions have nearly the same properties as those made by means of fixed oils.

They have no action on the metals, and

seem scarcely capable of combining with the metallic oxides.

They combine only imperfectly, and in small quantities, with alkalies and earths. The French chemists have proposed to give these combinations the name of savonules, which Dr. Pearson has translated by the term saponules; but these denominations have not been adopted by chemists.

They absorb nitrous gas in great abundance, and with great facility, and seemingly decompose it, acquiring a thick consistence and a resinous appearance, as if they had absorbed oxygen.

Sulphuric acid decomposes volatile oils; carbureted hydrogen gas is emitted, and charcoal is precipitated. Nitric acid inflames them, and converts them into water, carbonic acid, and charcoal. Oxymuriatic acid converts them into substances analogous to resins.

Volatile oils are applied to a great number of uses. Some of them are employed in medicine; some of them, as oil of turpentine, are much used to dissolve resins, which are afterwards employed as varnishes; not to mention their employment in painting and in perfumery.

Besides the oils which exist ready formed in the vegetable and animal kingdoms, there are a variety of others which are obtained when animal or vegetable bodies are distilled by means of a heat above that of boiling water. These oils have received the appellation of empyreumatic, because they are formed by the action of the fire.

The following is a list of the plants which yield the fixed oils occurring usually in commerce:

1. Linum usitatissimum & perenne - -	Linseed oil
2. Corylus avellana 3. Juglans regia	Nut oil
4. Papaver somniferum -	Poppy oil
5. Cannabis sativa - -	Hemp oil
6. Sesamum orientale -	Oil of sesamum
7. Olea Europea - -	Olive oil
8. Amygdalus communis -	Almond oil
9. Guilandina Mohringa -	Oil of behen
10. Cucurbita pepo & melapepo	Cucumber oil
11. Fagus sylvatica - -	Beech oil
12. Sinapis nigra & arvensis	Oil of mustard
13. Helianthus annuus & perennis - -	Oil of sunflower
14. Brassica napus & campestris	Rapeseed oil
15. Ricinus communis -	Castor oil
16. Nicotiana tabacum & rustica - - -	Tobacco-seed oil
17. Prunus domestica -	Plum-kernel oil
18. Vitis vinifera - -	Grapeseed oil
19. Theobroma cacao -	Butter of cacao
20. Laurus nobilis - -	Laurel oil
21. Arachis hypogæa - -	Ground-nut oil.

The following Table contains a copious list of plants which yield volatile oils. The part of the plant from which it is extracted, and the English name of the oil, are added in separate columns.

Plants.	Parts.	Oil of	Colour.
1. Artemisia absynthium -	Leaves -	Wormood -	Green
2. Acorus calamus - - - -	Root -	Sweet flag -	Yellow
3. Myrtus pimenta - - -	Fruit -	Jamaica pepper	Yellow
4. Ancthum graveolens - -	Seeds -	Dill - -	Yellow
5. Angelica archangelica - -	Root -	Angelica	
6. Pimpinella anisum - -	Seeds -	Anise - -	White
7. Illicium anisatum - - -	Seeds -	Stellat. anise	Brown
8. Artemisia vulgaris - - -	Leaves -	Mugwort	
9. Citrus aurantium - - -	Rind of the fruit	Bergamot -	Yellow
10. Meloleuca leucodendra -	Leaves -	Cajeput - -	Green
11. Eugenia caryophyllata -	Capsules -	Cloves - -	Yellow
12. Carum carui - - - - -	Seeds -	Caraways -	Yellow
13. Amomum cardamomum -	Seeds -	Card. seeds -	Yellow
14. Carlina acaulis - - - -	Roots -	- - - -	White
15. Scandix chaerefolium - -	Leaves -	Chervil - -	Sulph. yellow
16. Matricaria chamomilla -	Petals -	Chamomile -	Blue
17. Laurus cinnamomum - -	Bark -	Cinnamon -	Yellow
18. Citrus medica - - - -	Rind of the fruit	Lemons - -	Yellow
19. Cochlearia officinalis - -	Leaves -	Scurvy grass -	Yellow
20. Copaifera officinalis - -	Extract -	Copaiba	White
21. Coriandrum sativum - -	Seeds -	Coriand. seed	White
22. Crocus sativus - - - -	Pistils -	Saffron - -	Yellow
23. Piper cubeba - - - -	Seeds -	Cubeb pepper	Yellow
24. Laurus culilaban - - -	Bark -	Culilaban -	Brown yellow
25. Cuminum cymium - - -	Seeds -	Cummi - -	Yellow
26. Inula helenium - - - -	Roots -	Elecampane -	White
27. Anethum fœniculum -	Seeds -	Fennel - -	White
28. Croton eleutheria - - -	Bark -	Cascarilla -	Yellow
29. Maranta galanga - - -	Roots -	Galanga -	Yellow
30. Hyssopus officinalis - -	Leaves -	Hyssop - -	Yellow
31. Juniperus communis - -	Seeds -	Juniper - -	Green
32. Lavendula spica - - -	Flowers -	Lavender -	Yellow
33. Laurus nobilis - - - -	Berries -	Laurel - -	Brownish
34. Prunus laurocerasus - -	Leaves -	Laurocerasus	
35. Levisticum logusticum -	Roots -	Loveage -	Yellow
36. Myristica moschata - -	Seeds -	Mace - -	Yellow
37. Origanum majorana - -	Leaves -	Marjoram -	Yellow
38. Pistacia lentiscus - - -	Resin -	Mastich -	Yellow
39. Matricaria parthenium -	Plant -	Motherwort -	Blue
40. Melissa officinalis - - -	Leaves -	Balm - -	White
41. Mentha crispa - - - -	Leaves -	- - -	White
42. ——— piperitis - - -	Leaves -	Peppermint -	Yellow
43. Achillea millefolium - -	Flowers -	Millefoil -	Blue and green
44. Citrus aurantium - - -	Leaves -	Neroli - -	Orange
45. Origanum creticum - -	Flowers -	Spanish hop -	Brown
46. Apium petroselinum - -	Roots -	Parsley - -	Yellow
47. Pinus sylvestris & abies -	Wood and resin	Turpentine -	Colourless
48. Piper nigrum - - - -	Seeds -	Pepper - -	Yellow
49. Rosmarinus officinalis - -	Plant -	Rosemary -	Colourless
50. Mentha pulegium - - -	Flowers -	Pennyroyal -	Yellow
51. Genista canariensis - - -	Root -	Rhodium -	Yellow
52. Rosa centifolia - - -	Petals -	Roses - -	Colourless
53. Ruta graveolens - - -	Leaves -	Rue - -	Yellow
54. Juniperus sabina - - -	Leaves -	Savine - -	Yellow
55. Salvia officinalis - - -	Leaves -	Sage - -	Green.
56. Santalum album - - -	Wood -	Santalum -	Yellow
57. Laurus sassafras - - - -	Root -	Sassafras -	Yellow
58. Satureia hortensis - - -	Leaves -	Satureia -	Yellow
59. Thymus serpillum - - -	Leaves & flowers	Thyme - -	Yellow
60. Valeriana officinalis - -	Root -	Valerian -	Green
61. Kæmpferia rotunda - -	Root -	Zedoary -	Greenish blue
62. Amomum Zinziber - -	Root -	Ginger - -	Yellow
63. Andropogon schænanthum	- - -	Sira - -	Brown.

Several of the gum-resins, as myrrh and galbanum, yield an essential oil; and likewise the balsams, as benzoin, &c.

Oil-mill. See Olea.

OLAX, a genus of the triandria monogynia class and order. The calyx is entire, trifid; corolla funnel-form, trifid; nect. four; berry three-celled, many-seeded. There is one species, a tree of Ceylon.

OLDENLANDIA, a genus of the tetrandria monogynia class and order. Its characters are these: the empalement of the flower is permanent, sitting upon the germen; the flower has four oval petals, which spread open, and four stamina, terminated by small summits; it has a roundish germen, situated under the flower, crowned by an indented stigma: the germen afterwards turns to a globular capsule, with two cells filled with small seeds. There are sixteen species, herbs of the Cape, &c.

OLD-WIFE, or Wrasse. See Labrus.

OLEA, the *olive-tree*, a genus of the monogynia order, in the diandria class of plants; and in the natural method ranking under the 44th order, sapieriæ. The corolla is quadrifid, with the segments nearly ovate. The fruit is a monospermous plum. There are seven species; the most remarkable are:

1. The Europea, or common olive-tree, rises with upright solid stems, branching numerously on every side, 20 or 30 feet high; spear-shaped, stiff, opposite leaves, two or three inches long, and half an inch or more broad; and at the axillas small clusters of white flowers, succeeded by oval fruit. This species is the principal sort cultivated for its fruit; the varieties of which are numerous, varying in size, colour, and quality. It is a native of the southern parts of Europe, and is cultivated in great quantities in the south of France, Italy, and Portugal, for the fruit to make the olive-oil.

2. The capensis, or Cape box-leaved olive.
3. Olea odoratissima, the flower of which is by some said to give the fine flavour to the green tea; but Thunberg attributes the flavour to the cemellie seserque.

Olive-trees are easily propagated by shoots, which, when care has been taken to ingraft them properly, bear fruit in the space of eight or ten years. Those kinds of olive-trees which produce the purest oil, and bear the greatest quantity of fruit, are ingrafted on the stocks of inferior kinds. Different names are assigned by the French to the different varieties of the olive-tree; and of these they reckon 19, whilst in Florence are cultivated no fewer than 32. Olive-shoots are ingrafted when in flower; if the operation has been delayed, and the tree bears fruit, it is thought sufficient to take off a ring of bark, two fingers' breadth in extent, above the highest graff. In that case the branches do not decay the first year; they afford nourishment to the fruit, and are not lopped off till the following spring. Olive-trees are commonly planted in the form of a quincunx, and in rows at a considerable distance from one another. Between the rows it is usual to plant vines, or to sow some kind of grain. It is observed, that olives, like many other fruit-trees, bear well only once in two years. The whole art of dressing these trees consists in removing the superfluous wood; for it is remarked, that trees loaded with too much wood produce neither so much fruit nor of so good a quality. Their propagation in England is commonly by layers.

Olives have an acrid, bitter, and extremely disagreeable taste; pickled (as we receive them from abroad) they prove less disagreeable. The Lucca olives, which are smaller than the others, have the weakest taste; the Spanish, or larger, the strongest; the Provence, which are of a middling size, are generally the most esteemed.

When olives are intended for preservation, they are gathered before they are ripe. The art of preparing them consists in removing their bitterness, in preserving them green, and in impregnating them with a brine of aromatised sea-salt, which gives them an agreeable taste. For this purpose, different methods are employed: formerly they used a mixture of a pound of quicklime, with six pounds of newly sifted woodashes; but of late, instead of the ashes, they employ nothing but a ley. This, it is alleged, softens the olives, makes them more agreeable to the taste, and less hurtful to the constitution. In some parts of Provence, after the olives have lain some time in the brine, they remove them, take out the kernel, and put a caper in its place. These olives they preserve in excellent oil; and when thus prepared, they strongly stimulate the appetite in winter. Olives perfectly ripe are soft, and of a dark red colour. They are then eaten without any preparation, excepting only a seasoning of pepper, salt, and oil; for they are extremely tart, bitter, and corrosive.

The oil is undoubtedly that part of the produce of olive-trees which is of greatest value. The quality of it depends on the nature of the soil where the trees grow, on the kind of olive from which it is expressed, on the care which is taken in the gathering and pressing of the fruit, and likewise on the separation of the part to be extracted. Unripe olives give an intolerable bitterness to the oil; when they are over-ripe, the oil has an unguinous taste; it is therefore of importance to choose the true point of maturity. When the situation is favourable, those species of olives are cultivated which yield fine oils; otherwise they cultivate such species of trees as bear a great quantity of fruit, and they extract oil from it, for the use of soaperies, and for lamps.

They gather the olives about the months of November or December. It is best to put them as soon as possible into baskets, or into bags made of wool or hair, and to press them immediately, in order to extract a fine oil. Those who make oil only for soaperies, let them remain in heaps for some time in their storehouses; when afterwards pressed, they yield a much greater quantity for oil. In order to obtain the oil, the olives are first bruised in a round trough, under a millstone, rolling perpendicularly over them; and when sufficiently mashed, put into the maye, or trough, *m*, of an olive-press (Plate Miscel. fig. 177), where *aa* are the upright beams, or cheeks; *b* the female, and *c* the male screw; *e*, the bar for turning the screw; *f*, the board on which the screw presses; *g*, a cubical piece of wood, called a block; *h*, the peel, a circular board to be put under the block. By turning the screw, all the liquor is pressed out of the mashed olives, and is called virgin-oil; after which, hot water being poured upon the remainder in the press, a coarser oil is obtained. Olive-oil keeps only about a year, after which it degenerates.

Oil of olives is an ingredient in the composition of a great many balsams, ointments, plasters, mollifying and relaxing liniments. It is of an emollient and solvent nature; mitigates gripes of the colic, and the pains accompanying dysentery; and is supposed a good remedy when any person has chanced to swallow corrosive poisons. It is an effectual cure for the bite of a viper; and, as M. Bourgeois tells us, for the sting of wasps, bees, and other insects. A bandage soaked in the oil is immediately applied to the sting, and a cure is obtained without any inflammation or swelling. Olive-oil is of no use in painting, because it never dries completely. The best soap is made of it, mixed with Alicant salt-wort and quicklime.

OLERON, *sea laws of*, certain laws relating to maritime affairs, made in the time of Richard I. when he was at the island of Oleron.

These laws, being accounted the most excellent sea-laws in the world, are recorded in the black book of the admiralty.

OLIBANUM, a dry resinous substance obtained from the juniperus lycia, and chiefly collected in Arabia. It is the frankincense of the antients. It is in transparent brittle masses about the size of a chesnut. Its colour is yellow. It has little taste, and when burnt diffuses an agreeable odour. Alcohol dissolves it; and with water it forms a milky liquid. When distilled, it yields a small quantity of volatile oil. Specific gravity, 1.73.

OLIVE. See Olea.

OLYMPIC Games, were solemn games, famous among the antient Greeks, so called from Olympian Jupiter, to whom they were dedicated.

OLYRA, a genus of the triandria order, in the monœcia class of plants, and in the natural method ranking under the 4th order, gramina. The male calyx is a biflorous and aristated glume; the corolla a beardless glume; the female calyx is an uniflorous, patulous, and ovate glume; the style is bifid, and the seed cartilaginous. There are two species, herbs of Jamaica.

OMBRE, a game at cards, played by 2, 3, or 5 persons; in all other respects resembling quadrille.

OMENTUM. See Anatomy.

OMNIUM, a term in use among stock-jobbers to express all the articles included in the contract between government and the original subscribers to a loan, which of late years has generally consisted of different proportions of 3 and 4 per cent. stock, with a certain quantity of terminable annuities. Those who dispose of their share soon after the agreement is concluded, generally get a premium of 2 or 3 per cent. for it, which fluctuates with the current prices of the public funds; and in a few instances the omnium has been at a considerable discount. Some of the subscribers pay their whole subscription at the time fixed for the first or second payment, and their shares become immediately transferable stock: others dispose of the several articles which make up the terms of the loan, separately; and in this state the 3 or 4 per cent. consols, &c. are distinguished by the name of scrip, till the whole sum has been paid in upon them.

OMPHALEA, a genus of the triandria order, in the monœcia class of plants, and in the natural method ranking with those of which the order is doubtful. The male calyx is tetraphyllous; there is no corolla; the receptacle, into which the antheræ are sunk, is ovate. The female calyx and corolla are as in the male; the stigma trifid; the capsule carnous and trilocular, with one seed. There are four species, shrubs of Jamaica.

ONCHIDIUM, a genus of insects of the order vermes mollusca: the generic character is; body oblong, creeping, flat beneath, mouth placed before; feelers two, situated above the mouth; arms two, at the sides of the head; vent behind, and placed beneath. The onchidium typhæ, the only species, inhabits Bengal, on the leaves of the typha elephantina, about an inch long, and three-quarters of an inch broad, but linear and longer when creeping. In appearance it very much resembles a limax, but differs principally in wanting the shield and lateral pore, and in being furnished with a vent behind.

Body above convex, beneath flat and smooth; head small, and placed beneath, which, when the animal is in motion, is perpetually changing its form and size, and drawn in when at rest; mouth placed lengthways, and continually varying its shape from circular to linear; feelers retractile, resembling those of a slug, and apparently tipt with eyes; arms dilatable, solid, compressed, and somewhat palmate when fully expanded.

ONION. See ALLIUM.

ONISCUS, a genus of insects of the order aptera: the generic character is; legs fourteen; antennæ setaceous; body oval. Of this genus, which consists of more than 40 species, the best known is the oniscus asellus, popularly known by the name of the woodlouse. It is a very common insect in gardens, fields, &c. and is observed in great quantities under the barks of decayed trees, beneath stones in damp situations, &c. Its general length is about half an inch, or rather more, and its colour livid brown, the larger specimens often exhibiting a double series of pale spots down the back: like the rest of the genus, it preys on the minuter insects.

2. Oniscus armadillo, or the medical woodlouse, is of somewhat larger size than the preceding, much darker colour, and of a polished surface: it is equally common with the preceding species, and is found in similar situations; when suddenly disturbed or handled, it rolls itself up into a completely globular form, in the manner of the curious quadrupeds called armadilios, frequently remaining in this state for a very considerable length of time, or so long as it is any ways disturbed. Swammerdam relates a ludicrous mistake of a servant-maid, who, finding in the garden a great many in this globular state, imagined she had discovered some handsome materials for a necklace, and betook herself to stringing them with great care; but on suddenly perceiving them unfold, was seized with a panic, and ran shrieking into the house.

Though considered as of but slight importance in the present practice of physic, these animals once maintained a very respectable station in the materia medica, under the title of millepedes.

3. Oniscus aquaticus is a native of the clearer kind of stagnant waters, and is of the general size and colour of the oniscus asellus, but of a more lengthened form, and with longer limbs in proportion; the two last legs being bifid. This species is viviparous, and of a considerably prolific nature.

Among the marine insects of this genus the largest is the oniscus entomon, measuring two inches in length: its general form and colour resemble that of the oniscus asellus, but the four lower pair of legs are longer in proportion, the three first pair being very small and short; the tail is long and pointed. It is a native of the European seas, and is found about rocks, &c. It is of a strong fabric, the divisions of the upper part being of an almost calcareous nature. This animal is capable of living several days in fresh water.

ONOCLEA, a genus of the class and order cryptogamia filices. The capsules are under the recurved and contracted pinnules of the frond, resembling pericarps. There are two species.

ONONIS, or ANONIS, *rest-harrow*, in botany. See ANONIS.

ONOPORDUM, a genus of the class and order syngenesia polygamia æqualis. The essential character is, calyx scales mucronate; recept. honey-combed. There are seven species, one of them well-known under the name of cotton-thistle or pig-leaves.

ONOSMA, a genus of the monogynia order, in the pentandria class of plants, and in the natural method ranking under the 41st order, asperifoliæ. The corolla is campanulated, with the throat pervious: there are four seeds. There are three species, rock plants of the South of Europe.

ONYX, in natural history, one of the semipellucid gems, with variously-coloured zones, but none red; being composed of crystal, debased by a small admixture of earth, and made up either of a number of flat plates, or of a series of coats surrounding a central nucleus, and separated from each other by veins of a different colour, resembling zones or belts. We have four species of this gem: 1. A blueish-white one, with broad white zones. 2. A very pure onyx, with snow-white veins. 3. The jasponyx, or horny onyx, with green zones. 4. The brown onyx, with blueish-white zones. The antients attributed wonderful properties to the onyx, and imagined that if worn on the finger it acted as a cardiac; they have also recommended it as an astringent, but at present no regard is paid to it. The word in the Greek language signifies nail; the poets feigning this stone to have been formed by the Parcæ from a piece of Venus's nails, cut off by Cupid with one of his arrows. See CHALCEDONY.

OOLITE. See PISOLITE.

OPACITY, in philosophy, a quality of bodies which renders them impervious to the rays of light.

The cause of opacity in bodies does not consist, as was formerly supposed, in the want of rectilinear pores, pervious every way; but either in the unequal density of the parts, in the magnitude of the pores, or in their being filled with a matter, by means of which the rays of light in their passage are arrested by innumerable refractions and reflections, become extinct, and are absorbed.

OPAL, in mineralogy: this stone is found in many parts of Europe, especially in Hungary, in the Crapacks near the village of Czennizka. When first dug out of the earth it is soft, but it hardens and diminishes in bulk by exposure to the air. The substance in which it is found is a ferruginous sand-stone.

The opal is always amorphous. Its fracture is conchoidal. Commonly somewhat transparent. Specific gravity from 1.958 to 2.540. The lowness of its specific gravity, in some cases, is to be ascribed to accidental cavities which the stone contains. These are sometimes filled with drops of water. Some specimens of opal have the property of emitting various-coloured rays, with a particular effulgency, when placed between the eye and the light. The opals which possess this property are distinguished by lapidaries by the epithet Oriental; and often by mineralogists by the epithet nobilis. This property rendered the stone much esteemed by the antients. Opals acquire it by exposure to the sun. Werner has divided this species into five subspecies:

1. Noble opal. Lustre internal, glassy. Colour, usually light bluish-white. When its position is varied, it reflects the light of various bright colours. Brittle. Specific gravity 2.114. Does not melt before the blowpipe. When heated it becomes opaque, and sometimes is decomposed by the action of the atmosphere. Hence it seems to follow that water enters essentially into its composition. A specimen of this variety, analysed by Klaproth, contained

90	silica,
10	water
100.	

2. Common opal. Fracture imperfectly conchoidal. Lustre external and internal, glassy or greasy. Its colours are very various; milk-white, yellows, reds, greens of different kinds. Infusible by the blowpipe.

Specimens of this variety sometimes occur with rifts: these readily imbibe water, and therefore adhere to the tongue. Some opals gradually become opaque, but recover their transparency when soaked in water by imbibing that fluid. They are then called hydrophanes, or oculi mundi. The constituents of the common opal, as ascertained by Klaproth, are

Opal of Kosemutz.		Opal of Telkobanya.	
98.75	-	93.5	silica
0.1	-	1.0	oxide of iron
0.1	-	0.0	alumina
0.0	-	5.0	water.
98.95		99.5	

3. Semi-opal. Colours, various shades of white, grey, yellow, red, brown, often mixed together. Lustre glassy, sometimes greasy. Fracture imperfectly conchoidal. Brittle. Sometimes adheres to the tongue. Specific gravity 2.540. Infusible before the blowpipe. Its constituents, as ascertained by Klaproth, are,

Semiopal of Telkobanya		Of Menal-montant.	
43.5	-	85.5	silica
47.0	-	0.5	oxide of iron
7.5	-	11.0	water
		1.0	alumina
98.0		0.5	lime.
		98.5	

4. Holz-opal or wood-opal. Colours, various shades of white, grey, brown, yellow, red. Found in large pieces, which have the form of wood. Lustre glassy, sometimes greasy. Fracture in one direction conchoidal, in another exhibiting the texture of wood. Usually opaque. Brittle. Considered as fragments of wood impregnated with semi-opal.

5. Under the opal may be placed also the mineral known by the name of cat's-eye. It comes from Ceylon, and is seldom seen by European mineralogists till it has been polished by the lapidary. Mr. Klaproth has described a specimen which he received in its natural state from Mr. Greville of London. Its figure was nearly square, with sharp edges, a rough surface, and a good deal of brilliancy. Its texture is imperfectly foliated. Lustre greasy. Specific gravity 2.625 to 2.66. Colour grey, with a tinge of green, yellow, or white; or brown, with a tinge of yellow or red. In certain positions it re-

fects a splendid white, as does the eye of a cat: hence the name of this stone.

Two specimens analysed by Klaproth, the first from Ceylon, the other from Malabar, were compo ed of

95.00	94.50	silica
1.75	2.00	alumina
1.50	1.50	lime
0.25	0.25	oxide of iron.
98.5	98.25	

OPATRUM, a genus of insects of the coleoptera order; the generic character is: antennæ moniliform, thicker towards the top; head projecting from a cavity in the thorax; thorax a little flattened, margined; shells immarginate, longer than the abdomen. There are about 28 species of this genus.

OPERATION. See SURGERY.

OPERATIONS in chemistry. See CHEMISTRY.

OPERCULARIA, a genus of the class and order tetrandria monogynia: the flower is compound; calyx common, one-leafed. There are three species, insignificant herbs of New Holland, &c.

OPHICEPHALUS, a genus of fishes of the order thoracici; the generic character is: head coated with dissimilar scales; body elongated.

1. Ophicephalus punctatus: length about ten inches; dorsal fin commencing at no great distance from the head, and continued nearly to the tail; it is of moderate breadth, and of a dusky colour spotted with black; anal fin of similar shape and colour. Native of India, inhabiting rivers and lakes, and considered as a delicate and wholesome food.

2. Ophicephalus striatus: length about 12 inches; shape rather longer than that of the preceding species. Native of India, inhabiting lakes, where it often grows to a much larger size than first mentioned. It is in equal esteem as a food with the former species, and even recommended as a proper diet for convalescents. Native name wrahl. There is one other species.

OPHIDIUM, a genus of fishes of the order apodes; the generic character is: head somewhat naked; teeth in the jaws, palate, and throat; branchiostegous membrane seven-rayed, patulous; body ensiform.

1. Ophidium barbatum: the head of this fish is small; the upper jaw rather longer than the lower, and both beset with a great many small teeth; the lips are strong and fleshy; in the throat are several small teeth; between the eyes and mouth are four small pores. It is commonly found of the length of eight or nine inches, and sometimes twelve or fourteen; and is met with in all parts of the Mediterranean sea, and in great plenty in the Adriatic. It is often taken by nets in Provence and Languedoc with other kinds of fish, and is most common during the summer season. It is not considered as an elegant fish for the table, the flesh being rather coarse. It feeds on small fishes, crabs, &c. &c.

The ophidium aculeatum, or prickly ophidium, inhabits the fresh rivers in India, feeds on worms and a fat kind of earth, is esculent and long. See Plate Nat. Hist. fig. 300. There are four species.

OPHIOGLOSSUM, *adder's tongue*, a genus of the natural order of filices, in the cryptogamia class of plants. The spike is articulated, flat, and turned to the two sides, with the articuli or joints opening across. There are nine species, of which the only remarkable one is the vulgatum, or common adder's-tongue, which is a native of several places of Britain, growing in meadows and moist pastures. The country-people make an ointment of the fresh leaves, and use it as a vulnerary to green wounds.

OPHIORHIZA, a genus of the monogynia order, in the pentandria class of plants, and in the natural method ranking under the 47th order, stellatæ. The corolla is funnel-shaped; the capsule twin, bilocular, and polyspermous. There are three species, the most remarkable of which is the Asiaticum, or true lignum colubrinum. The root of this is known in the East Indies to be a specific against the poison of that most dreadful animal called the hooded serpent.

The true root is called mungus, for the following reason: There is a kind of weasel in the East Indies, called mungutia by the natives, mungo by the Portuguese, and muncas by the Dutch. This animal pursues the hooded serpent, as the cat does the mouse with us. As soon as the serpent appears, the weasel attacks him; and if she chances to be bitten by him, she immediately runs to find a certain vegetable, upon eating which she returns, and renews the fight. That celebrated traveller Kæmpfer, who kept one of these weasels tame, that ate with him, lived with him, and was his companion wherever he went, says he saw one of these battles between her and the serpent, but could not certainly find out what root the weasel looked out for. But whether the weasel first discovered this antidote or not, it is an infallible remedy against the bite of the hooded serpent. And this he undertakes to ascertain.

OPHIOXYLUM, a genus of the monœcia order, in the polygamia class of plants, and in the natural method ranking with those of which the order is doubtful. The hermaphrodite calyx is quinquefid; the corolla quinquefid and funnel-shaped, with a cylindrical nectarium within its mouth. There are two species, shrubs of the East Indies.

OPHIRA, a genus of the monogynia order, in the octandria class of plants. The involucrum is bivalvular and triflorous; the corolla is tetrapetalous above; the berry unilocular. There is one species, a shrub of Africa.

OPHITES, in church history, christian heretics, so called both from the veneration they had for the serpent that tempted Eve, and the worship they paid to a real serpent. They pretended that the serpent was Jesus Christ, and that he taught men the knowledge of good and evil. They distinguished between Jesus and Christ: Jesus they said was born of the Virgin, but Christ came down from heaven to be united with him; Jesus was crucified, but Christ had left him to return to heaven.

OPHRYS, *twyblade*, a genus of the diandria order, in the gynandria class of plants, and in the natural method ranking under the 7th order, orchideæ. The nectarium is a little carinated below. There are 34 species; but the most remarkable are the following: 1. The ovata, oval-leaved ophrys, or common twyblade, has a bulbous fibrated root, crowned by two oval, broad, obtuse, veined, opposite leaves; an erect, succulent, green stalk, six or eight inches high, naked above, and terminated by a loose spike of greenish flowers, having the lip of the nectarium bifid. The flowers of this species resemble the figure of gnats. 2. The spiralis, spiral orchis, or triple ladies'-tresses, with a cluster of oval, pointed, ribbed leaves; erect simple stalks, half a foot high, terminated by long spikes of white odoriferous flowers, hanging to one side, having the lip of the nectarium entire, and crenated. 3. The nidus-avis, or bird's-nest; with loose spikes of pale-brown flowers, having the lip of the nectarium bifid. 4. The anthropophora, man-shaped ophrys, or man-orchis; with spikes of greenish flowers, representing the figure of a naked man: the lip of the nectarium linear, tripartite, with the middle segment longest and bifid. There is a variety with brownish flowers tinged with green. 5. The insectifera, or insect-orchis, has spikes of insect-shaped greenish flowers, having the lip of the nectarium almost five-lobed. This wonderful species exhibits flowers in different varieties, that represent singular figures of flies, bees, and other insects, and are of different colours in the varieties. 6. The monorchis, or musky ophrys, with a loose spike of yellowish musky-scented flowers.

OPHTHALMIA. See MEDICINE.

OPIUM. See NARCOTIC PRINCIPLE, PAPAVER, and MATERIA MEDICA.

OPOBALSAMUM, or *balm of Gilead*, a resin obtained from the amyris Gileadensis, a tree which grows in Arabia, especially near Mecca. It is so much valued by the Turks, that it is rarely imported into Europe. Little is therefore known of its composition. It is said to be at first turbid and white, and of a strong aromatic smell, and of a bitter, acrid, astringent taste; but by keeping, it becomes limpid and thin, and its colours change first to green, then to yellow, and at last it assumes the colour of honey.

OPOPONAX, a resin obtained from the pastinaca opoponax, a plant which is a native of the countries round the Levant. The gum-resin is obtained by wounding the roots of the plant. The milky juice, when dried in the sun, constitutes the opoponax. It is in lumps of a reddish-yellow colour, and white within: taste bitter and acrid. With water it forms a milky solution. Its specific gravity is 1.62.

OPOSSUM. See DIDELPHIS.

OPPOSITE SECTIONS, are two hyperbolas made by cutting two opposite cones by the same plane. See CONIC SECTIONS.

OPPOSITION, in astronomy, is that aspect or situation of two stars or planets, wherein they are diametrically opposite to each other, or 180° asunder.

OPPOSITION, in geometry, the relation of two things, between which a line may be drawn perpendicular to both.

OPTATIVE MOOD, in grammar, that which serves to express an ardent desire or wish for something. In the English language we have neither optative nor subjunctive mood.

OPTICS, the science which explains the properties of light.

Optical definitions and principles.

1. Light is a matter, the particles of which

are extremely small, and by striking on our visual organs, give us the sensation of seeing.

2. The particles of light are emitted from what are called luminous bodies, such as the sun, a fire, a torch, or candle, &c. &c. It is reflected or sent back by what are termed opake bodies, or those which have no power of affording light in themselves.

3. Light, whether emitted or reflected, always moves in straight or direct lines, as may easily be proved by looking into a bent tube, which evidently obstructs the progress of the light in direct lines.

4. By a ray of light, is usually meant the least particle of light that can be either intercepted or separated from the rest. A beam of light is generally used to express something of an aggregate or mass of light greater than a single ray.

5. Parallel rays are such as proceed equally distant from each other through their whole course. The distance of the sun from the earth is so immense, that rays proceeding from the body of that luminary are generally regarded as parallel.

6. Converging rays are such as, proceeding from any body, approach nearer and nearer to each other, and tend to unite in a point. The form of rays thus tending to an union in a single point has been compared to that of a candle-extinguisher; it is in fact a perfect cone.

7. Diverging rays are those which, proceeding from a point, continue to recede from each other, and exhibit the form of an inverted cone.

8. A small object, or a small single point of an object, from which rays of light diverge, or indeed proceed in any direction, is sometimes called the radiant, or radiant point.

9. Any parcel of rays, diverging from a point, considered as separate from the rest, is called a pencil of rays.

10. The focus of rays is that point to which converging rays tend, and in which they unite and intersect, or cross each other. It may be considered as the apex or point of the cone; and it is called the focus (or fire-place), because it is the point at which burning-glasses burn most intensely.

11. The virtual or imaginary focus is that supposed point behind a mirror or looking-glass, where the rays would have naturally united, had they not been intercepted by the mirror.

12. Plane mirrors or speculums are those reflecting bodies, the surfaces of which are perfectly plain or even, such as our common looking-glasses. Convex and concave mirrors are those the surfaces of which are curved.

13. An incident ray is that which comes from any body to the reflecting surface; the reflecting ray is that which is sent back or reflected.

14. The angle of incidence is the angle which is formed by the line which the incident ray describes in its progress, and a line drawn perpendicularly to the reflecting surface: and the angle of reflection is the angle formed by the same perpendicular and the reflected ray; thus, (Plate I. Optics, fig. 1) if *b u* is a reflecting surface, and *d c* an incident ray, then *d c* P is the angle of incidence, and *e c* P the angle of reflection.

15. By a medium opticians mean any thing which is transparent, such as void space, air, water, or glass, through which consequently the rays of light can pass in straight lines.

16. The refraction of the rays of light is their being bent, or attracted out of their course, in passing obliquely from one medium to another of a different density, and which causes objects to appear broken or distorted when part of them is seen in a different medium. It is from this property of light that a stick or an oar which is partly immersed in water, appears broken.

17. A lens is a transparent body of a different density from the surrounding medium, commonly of glass, and used by opticians to collect or disperse the rays of light. They are in general either convex, that is, thicker in the middle than at the edges, which collect, and by the force of refraction converge the rays, and consequently magnify; or concave, that is, thinner in the middle than at the edges, which by the refraction disperse the rays of light, and diminish the objects that are seen through them.

18. Vision is performed by a contrivance of this kind. The crystalline humour, which is seated in the fore-part of the human eye, immediately behind the pupil, is a perfect convex lens. As therefore every object is rendered visible by beams or pencils of light, which proceed or diverge from every radiant point of the object, the crystalline lens collects all these divergent rays, and causes them to converge on the back part of the eye, where the retina or optic nerve is spread out; and the points where each pencil of rays is made to converge on the retina, are exactly correspondent to the points of the object from which they proceed. As, however, from the great degree of convergence which this contrivance will produce, the pencils of light proceeding from the extreme points of the object will be made to cross each other before they reach the retina, the image on the retina is always inverted. (See Plate II. fig. 23.)

19. The magnitude of the image painted on the retina will also, it is evident, depend on the greatness or obtuseness of the angle under which the pencil of rays proceeding from the extreme points of the object enters the eye. For it is plain, that the more open or obtuse the angle is, the greater is the tendency of these rays to meet in a point and cross each other; and the sooner they cross each other after passing the crystalline lens, the larger will be the inverted image painted on the retina. (See Plate II. fig. 24.) The visual angle, therefore, is that which is made by two right lines drawn from the extreme points of any object to the eye; and on the measure of that angle, the apparent magnitude of every visible object will depend.

20. The prism used by opticians is a triangular piece of fine glass, which has the power of separating the rays of light.

History of discoveries. The most antient hypothesis which leads to the true theory of light and colours, is that of the Platonics, viz. that light, from whatever it proceeds, is propagated in right lines; and that when it is reflected from the surfaces of polished bodies, the angle of reflection is equal to the angle of incidence. To this may be added the opinion of Aristotle, who supposed that rainbows, haloes, and mock suns, were occasioned by the reflection of the sun's beams in different circumstances. We have reason to believe, that the use of convex glasses, both as magnifiers and as burning-glasses, was not unknown to the antients, though the theory was not understood. The magnifying power of glasses, and some other optical phenomena, were also largely treated of by Alhazen, an Arabic philosopher of the twelfth century. These observations were followed by those of Roger Bacon, who demonstrated by actual experiment, that a small segment of a glass globe would greatly assist the sight of old persons; and from the hints afforded by these two philosophers, it is not unreasonable to conclude, that the invention of spectacles proceeded. Concerning the actual author of this useful invention, we have no certain information; we only find, that it was generally known about the beginning of the fourteenth century.

In the year 1575, Maurolycus, a teacher of mathematics at Messina, published a treatise on optics, in which he demonstrates, that the crystalline humour of the eye is a lens, which collects the rays of light proceeding from external objects, and throws them on the retina, or optic nerve. From this principle he was led to discover the reason of what are called short and imperfect sights. In the one case, the rays converge too soon; in the other, they do not converge soon enough. Hence short-sighted persons are relieved by a concave glass, which causes the rays to diverge in some degree before they enter the eye, and renders it more difficult for them to converge so fast as they would have done after entering the crystalline humour. Hence too he proves that a convex lens is of use to persons who have weak but long sight, by causing the rays to converge sooner, and in a greater quantity, than would otherwise happen. He was the first also that solved a problem which had caused much perplexity in the antient schools, respecting the sun's image appearing round, though the rays that form it are transmitted into a dark room through an angular aperture. He considered, that as the rays of light are constantly proceeding, in every direction, from every part of the sun's disk, "they must be crossing each other from the extreme part of it in every point of the aperture; so that every such point will be the apex of two cones, of which the base of the one is the sun's disk, and that of the other his image on the opposite wall." The whole image, therefore, consists of a number of images, all of which are circular; the image of the sun formed of those images must be circular also; and it will approach the nearer a perfect circle, the smaller the aperture, and the more distant the image.

Nearly about the same time Johannes Baptista Porta, of Naples, invented the camera obscura; and his experiments upon that instrument convinced him that light is a substance, by the intromission of which into the eye, vision is performed; for it is proper to mention, that before his time the opinion was almost general, that vision depended upon what was termed visual rays, proceeding from the eye. In this the system of Porta corresponds nearly with that of Maurolycus: but it ought to be remarked, that the discoveries of each of these two philosophers were unknown to the other. He shews, moreover, that a defect of light is remedied by the dilatation of the pupil, which contracts involuntarily when exposed to a strong light, and opens when the light is faint and languid.

One Fletcher, of Breslau, in 1571, endeavoured to account for the phenomena of the rainbow, by a double reflection and one refraction; but Antonio de Dominis, whose treatise was published in 1611, was the first who came near to the true theory. He describes the progress of the ray of light through each drop of the falling rain; he shews that it enters the upper part of the drop, where it suffers one refraction; that it is reflected once, and then refracted again, so as to come directly to the eye of the spectator: why this refraction should produce the different colours, was reserved for sir Isaac Newton to explain.

The latter part of the sixteenth century was illustrious for the invention of telescopes. It is generally allowed to have been casual. That effect of refraction, which causes the rays of light, in passing through a dense medium thicker in the middle, to converge to a point, and also that which takes place when they pass through one thicker at the extremities, had been long observed; and the assistance which convex and concave glasses afforded to the sight, had brought them into common use. The inventor of the telescope is not certainly known. The most probable account is, that one Zacharias Jansen, a spectacle-maker of Middleburgh, trying the effect of a concave and convex glass united, found that, placed at a certain distance from each other, they had the property of bringing distant objects apparently nearer to the eye. An account which is very commonly received, is, that some of his children playing in his shop with spectacle-glasses, perceived that when they held two of these glasses between their fingers, at a certain distance from each other, the dial of the clock appeared greatly magnified, but in an inverted position. From this their father adopted the idea of adjusting two of these glasses on a board, so as to move them at pleasure. Telescopes were greatly improved by Galileo, who constructed one which magnified 33 times, and with this he made all his wonderful astronomical discoveries.

The rationale of telescopes was, however, not explained till Kepler, who described the nature and the degree of refraction, when light passed through denser or rarer mediums, the surfaces of which are convex or concave; namely, that it corresponds to the diameter of the circle of which the convexity or concavity are portions of arches. He suggested some improvements in the construction of telescopes, which, however, were left to others to put in practice.

To the Jansens we are also indebted for the discovery of the microscope; an instrument depending upon exactly the same principles as the former. In fact, it is not improbable, that the double lens was first applied to the observation of near but minute objects, and afterwards, on the same principles, to objects which appeared minute on account of their distance.

Much attention was given by Kepler to the investigation of the law of refraction; but he was able to advance no nearer the truth than the observation, that when the incident ray does not make an angle of more than 30 degrees with the perpendicular, the refracted ray proceeds in an angle which is about two-thirds of it. Many disputes arose about the time of Kepler (1600) upon this subject, but it appears that little was effected by them in the cause of truth.

Kepler was more successful in pursuing the discoveries of Maurolycus and B. Porta. He demonstrated that images of external objects were formed upon the optic nerve by the foci of rays coming from every part of the object: he also observed, that these images are inverted; but this circumstance, he says, is rectified by the mind, which, when an impression is made on the lower part of the retina, considers it as made by rays proceeding from the higher parts of the object. Habit is supposed to reconcile us to this deception, and to teach us to direct our hands to those parts of objects from which the rays proceed. Tycho Brahe, observing the apparent diminution of the moon's disc in solar eclipses, imagined that there was a real diminution of the disc by the force of the sun's rays; but Kepler said, that the disc of the moon does not appear less in consequence of being unenlightened, but rather that it appears at other times larger than it really is, in consequence of its being enlightened. For pencils of rays from such distant objects generally come to their foci before they reach the retina, and consequently diverge and spread when they reach it. For this reason, he adds, different persons may imagine the disc to be of different magnitudes, according to the relative goodness of their sight.

In the sixteenth century also many improvements were made in perspective; the ingenious device, in particular, of the reformation of distorted images by concave or convex speculums was invented, but it is uncertain by whom.

The true law of refraction was discovered by Snellius, the mathematical professor at Leyden; but not living to complete it, the discovery was published and explained by professor Hortensius. Some discoveries of lesser importance were made at this time, among others by Descartes, who very clearly explained the nature and cause of the figure of the rainbow, though he was able to give no account of the colours; he however considered the small portion of water, at which the ray issues, as having the effect of a prism, which was known to have the property of exhibiting the light, transmitted through it, coloured.

In 1625, the curious discovery of Scheiner was published at Rome, which ascertains the fact, that vision depends upon the images of external objects upon the retina. For taking the eye of an animal, and cutting away the coats of the back part, and presenting different objects before it, he displayed their images distinctly painted on the naked retina or optic nerve. The same philosopher demonstrated by experiment, that the pupil of the eye is enlarged in order to view remote objects, and contracted when we view those which are near. He shewed, that the rays proceeding from any object, and passing through a small hole in a pasteboard, cross one another before they enter the eye; for if the edge of a knife is held on the side next the eye, and is moved along till it in part covers the hole, it will first conceal from the eye that part of the object which is situated on the opposite side of the hole.

Towards the middle of the seventeenth century the velocity of light was discovered by some members of the Royal Academy of Sciences at Paris, particularly Cassini and Roemer, by observing the eclipses of Jupiter's satellites. About the same time Mr. Boyle made his experiments on colours. He proved that snow did not affect the eye by a native, but reflected light, a circumstance which, however, at this day, we should scarcely believe was ever necessary to be proved by experiment. By admitting also a ray of light into a dark room, and letting it fall on a sheet of paper, he demonstrated, that white reflected much more light than any other colour; and to prove that white bodies reflect the rays outwards, he adds, that common burning-glasses will not, for a long while, burn or discolour white paper; on the contrary, a concave mirror of black marble did not reflect the rays of the sun with near so much power as a common concave mirror. The same effect was verified by a tile, one half of the surface of which was white, and the other black.

Some experiments were made about this time on the difference of the refractive powers of bodies; and the first advance to the great discoveries by means of the prism was made by Grimaldi, who observed, that a beam of the sun's light, transmitted through a prism, instead of appearing round on the opposite wall, exhibited an oblong image of the sun. Towards the close of this century the reflecting telescope was invented by our countryman James Gregory. It was, however, only an idea conceived by him upon theory, and the first reflecting telescope was made by Newton.

The reader will soon perceive how very imperfect all the preceding discoveries were in comparison with those of sir Isaac Newton. Before this time, little or nothing was known concerning colours; even the remark of Grimaldi respecting the oblong figure of the sun, made by transmitting the rays through a prism, was unknown to our great philosopher, having been published only the year before. This fact, however, which he had observed himself, was, it appears, the first circumstance which directed the attention of Newton to the investigation of the theory of colours. Upon measuring the coloured image, which was made by the light admitted into a dark chamber through a prism, he found that its length was five times greater than its breadth. So unaccountable a circumstance induced him to try the effect of two prisms, and he found that the light, which by the first prism was diffused into an oblong, was by the second reduced to a circular form, as regularly as if it had passed through neither of them. After many conjectures and experiments relative to the cause of these phenomena, he at length applied to them what he calls the experimentum crucis. He took two boards, and placed one of them close to the window, so that the light might be admitted through a small hole made in it, and after passing through a prism might fall on the other board, which was placed at about twelve feet distance, and in which there was also a small aperture, in order that some of the incident light might pass through it. Behind this hole, in the second board, he also placed a prism, so that the light, after passing both the boards, might suffer a second refraction before it reached the wall. He then moved the first prism in such a manner as to make the several parts of the image cast upon the second board pass successively through the hole in it, that he might observe to what places on the wall the second prism would refract them. The consequence was, that the coloured light, which formed one end of the image, suffered a refraction considerably greater than that at the other end; in other words, rays or particles of light of one colour were found to be more refrangible than those of another. The true cause, therefore, of the length of the image was evident; since it was proved by the experiment, that light was not homogeneal, but consisted of different particles or rays, which were capable of different degrees of refrangibility, according to which they were transmitted through the prism to the opposite wall. It was further evident from these experiments, that as the rays of light differ in refrangibility, so they also differ in exhibiting particular colours, some rays producing the colour red, others that of yellow, blue, &c. and of these different-coloured rays, separated by means of the prism according to their different degrees of refrangibility, the oblong figure on the wall was composed. But to relate the great variety of experiments, by which he demonstrated these principles, or the extensive application of them, would lead us too much into detail; let it suffice to say, that he applied his principles to the satisfactory explanation of the colours of natural bodies, of the rainbow, and of most of the phenomena of nature where light and colour are concerned; and that almost every thing which we at present know upon these subjects was laid open by his experiments.

His observations on the different refractive powers of different substances are curious and profound; but chemistry was at that period scarcely in a state sufficiently advanced to warrant all his conclusions. The general result is, that all bodies seem to have their refractive powers proportional to their densities, excepting so far as they partake more or less of inflammable or oily particles.

The discovery of the different refrangibility of the component rays of light suggested defects in the construction of telescopes, which were before unthought of, and in the creative hand of a Newton led to some no less extraordinary improvements in them. It is evident, that since the rays of light are of different refrangibilities, the more refrangible will converge to a focus much sooner than the less refrangible, consequently that the whole beam cannot be brought to a focus in any one point; so that the focus of every object-glass will be a circular space of considerable diameter, namely, about one fifty-fifth of the aperture of the telescope. To remedy this, he adopted Gregory's idea of a reflector, with such improvements as have been the basis of all the present instruments of this kind.

When a science has been carried to a certain degree of perfection, subsequent discoveries are too apt to be considered as of little importance. The real philosopher will not, however, regard the discoveries on light and colours, since the time of Newton, as unworthy his attention. By a mere accident, a very extraordinary property in some bodies of imbibing light, and afterwards emitting it in the dark, was observed. A shoemaker of Bologna, being in quest of some chemical secret, calcined, among other things, some stones of a particular kind, which he found at the bottom of Mount Peteius; and casually observed, that when these stones were carried into a dark place, after having been exposed to the light, they possessed a self-illuminating power. Accident afterwards discovered the same property in other substances. Baldwin, of Misnia, dissolving chalk in aquafortis, found that the residuum, after distillation, exactly resembled the Bolognian stone in retaining and emitting light, whence it now has the name of Baldwin's phosphorus; and M. Du Fay observed the same property in all substances that could be reduced to a calx by burning only, or after solution in nitrous acid. These facts seem to establish the materiality of light.

Some very accurate calculations were made about the year 1725 by Dr. Bradley, which afforded a more convincing proof of the velocity of light, and the motion of the earth in its orbit. Nor must we forget M. Bouguer's very curious and accurate experiments for ascertaining the quantity of light which was lost by reflection, the most decisive of which was by admitting into a darkened chamber two rays of light, one of which he contrived should be reflected, and the other fall direct on the opposite wall; then by comparing the size of the apertures by which the light was admitted (that through which the direct ray proceeded being much smaller than that through which the reflected ray was suffered to pass, and the illumination on the wall being equal in both), he was enabled to form an exact estimate of the quantity of light which was lost. To prove the same effect with candles, he placed himself in a room perfectly dark, with a book in his hand, and having a candle lighted in the next room, he had it brought nearer to him till he could just see the letters, which were then 24 feet from the candle. He then received the light of the candle reflected by a looking-glass upon the book, and he found the whole distance of the book from the source of the light (including the distance from the book to the looking-glass) to be only 15 feet; whence he concluded, that the quantity of direct light is to that of reflected as 576 to 225; and similar methods were pursued by him for measuring the proportions of light in general.

The speculations of Mr. Melville concerning the blue shadows which appear from opaque bodies in the morning and evening, when the atmosphere is serene, are far from uninteresting. These phenomena he attributes to the power which the atmosphere possesses of reflecting the fainter and more refrangible rays of light, the blue, violet, &c. and upon this principle he also explained the blue colour of the sky, and some other phenomena.

The same period produced Mr. Dollond's great improvement in the construction of telescopes. It consists in using three glasses of different refractive powers, crown and flint glass, which correct each other. The great dispersion of the rays which the flint-glass produces, is the effect of the lead, and is in proportion to the quantity of that metal which is used in its composition. Mr. Martin found the refractive powers of different glasses to be in proportion to their specific gravity.

Several discoveries and improvements have been made since the time of Newton in that branch of optics which relates more immediately to vision. One of these is not only curious in itself, but led to the explanation of several circumstances relating to vision. M. De la Motte, a physician of Dantzick, was endeavouring to verify an experiment of Scheiner, in which a distant object appeared multiplied when viewed through several holes made with the point of a pin in a card, not further distant from one another than the diameter of the pupil of the eye; but notwithstanding all his labour, he was unable to succeed, till a friend happening to call upon him, he desired him to make the trial, and it answered perfectly. This friend was short-sighted; and when he applied a concave glass close to the card, the object, which seemed multiplied before, now appeared but one.

The last, though not least, successful adventurer in this branch of science, is Mr. Delaval, who, in a paper read before the Philosophical Society of Manchester, in 1784, has endeavoured, with great ingenuity, to explain the permanent colours of opaque bodies. The majority of those philosophers, who have treated of light and colours, have, he observes, supposed that certain bodies or surfaces reflected only one kind of rays, and therefore exhibited the phenomena of colours; on the contrary, Mr. Delaval, by a variety of well-conducted experiments, evinced, that colours are exhibited, not by reflected, but by transmitted light. This he proved by covering coloured glasses and other transparent coloured media, on the further surface, with some substance perfectly opaque, when he found they reflected no colour, but appeared perfectly black. He concludes, therefore, as the fibres or bases of all vegetable, mineral, and animal substances, are found, when cleared of heterogeneous matters, to be perfectly white; that the rays of light are in fact reflected from these white particles, through coloured media, with which they are covered; that these media serve to intercept and impede certain rays in their passage through them, while, a free passage being left to others, they exhibit, according to these circumstances, different colours. This he illustrates by the fact remarked by Dr. Halley, who, in diving deep into the sea, found that the upper part of his hand, when extended into the water from the diving-bell, reflected a deep-red colour, while the under part appeared perfectly green. The conclusion is, that the more refrangible rays were intercepted and reflected by particles contained in the sea-water, and were consequently reflected back by the under part of the hand; while the red rays, which were permitted to pass through the water, were in the same manner reflected by the upper part of the hand, which therefore appeared of a red rose-colour. Those media, our author thinks, transmit coloured light with the greatest strength, which have the strongest refractive power.

Of the nature of light. Numerous opinions have successively been adopted concerning this wonderful fluid. It has been sometimes considered as a distinct substance, sometimes as a quality, sometimes as a cause, frequently as an effect; by some regarded as a compound, and by others as a simple substance. Descartes and other philosophers of high repute, have imagined that the sensation which we receive from light is to be attributed entirely to the vibrations of a subtile medium or fluid, which is diffused throughout the universe, and which is put into action by the impulse of the sun. In this view they consider light as analogous to sound, which is known to depend entirely on the pulsations of the air upon the auditory nerves; and in support of this opinion, it has been even lately urged, 1st, That some diamonds, on being rubbed or chafed, are luminous in the dark. 2. That an electric spark, not larger, but much brighter, than the flame of a candle, may be produced, and yet that no part of the electric fluid is known to escape, in such a case, to distant places, but the whole proceeds in the direction to which it is destined by the hand of the operator. Weaker or stronger sparks of this fluid are also known to differ in colour; the strongest are white, and the weakest red, &c.

To this opinion, however, there are many pressing, and, indeed, insurmountable objections. 1st, The velocity of sound bears a very small proportion to that of light. Light travels, in the space of eight minutes, a distance in which sound could not be communicated in 17 years; and even our senses may convince us, if we attend to the explosion of gunpowder, &c. of the almost infinite velocity of the one compared with that of the other. 2dly, If light depended altogether on the vibrations of a fluid, no solid reason can be assigned why this fluid should cease to vibrate in the night, since the sun must always affect some part of the circumambient fluid, and produce a perpetual day. 3dly, The artifice of candles, lamps, &c. would be wholly unnecessary upon this hypothesis, since, by a quick motion of the hand, or of a machine contrived for this purpose, light might on all occasions be easily produced. 4thly, Would not a ray of light, admitted through a small aperture, put in motion, according to this theory, the whole fluid contained in a chamber? In fact, we know that light is propagated only in right lines; whereas sound, which depends upon vibration, is propagated in every direction. 5thly, The separation or extension of the rays, by means of the prism, can never be accounted for by the theory of a vibrating medium. 6thly, The texture of many bodies is actually changed by exposure to the light. The juice of a certain shell-fish contracts, it is well known, a very fine purple colour, when permitted to imbibe the rays of the sun; and the stronger the light is, the more perfect the colour. Pieces of cloth wetted with this fluid become purple, even though inclosed in glass, if the solar light only is admitted; but the effect is totally prevented by the intervention of the thinnest plates of metal, which exclude the light. Some of the preparations of silver, as luna cornea, will remain white if covered from the light, but contract a dark-purple colour when exposed to it; and even the colour of plants is derived from the light, since a plant which vegetates in darkness will be perfectly white. As colour is imparted by light, so it is also destroyed by it. It must have fallen within the observation of every reader, that silks and other stuffs of delicate colours, are greatly affected by the action of light. Experiments have been made upon the same stuffs by exposing them to both heat and moisture in the dark, and also by exposing them to the light in the vacuum of an air-pump, and it was found by all these experiments, that the change of colour was to be ascribed to the action of light. 7thly, With respect to the emission of light by diamonds and other stones, it is easily accounted for upon other principles; and the arguments founded upon the electric spark not being sensibly diminished, will meet with a satisfactory solution by considering the extreme rarity of light, and the minuteness of its particles.

It is, therefore, almost universally agreed by the moderns, that light consists of a number of extremely minute particles, which are actually projected from the luminous body, and act by their projectile force upon the optic nerve. Concerning the nature of these particles, or rather of the matter of which they consist, there is less unanimity in the philosophical world.

The first remarkable property of light is its amazing velocity. In the short space of one second a particle of light traverses an extent of 170,000 miles, which is so much swifter than the progress of a cannon-ball, that the light is enabled to pass a space in about eight minutes which could not be passed with the ordinary velocity of a cannon-ball in less than 32 years. The velocity of light is also found to be uniform, whether it is original, as from the sun, or reflected only, as from the planets.

The mode of calculating the velocity of light is a branch of astronomy. It will suffice, therefore, in this place to remark, that by mathematical observations made upon the transits of Venus in 1761 and 1769, the diameter of the earth's orbit was found to be about 163,636,800 geographical miles. When, therefore, the earth happens to be on that side of her orbit which is opposite to Jupiter, an eclipse of his satellites, or any other appearance in that planet, is observed to take place 15 or 16 minutes later than it would have done if the earth had been on that side of her orbit which is nearest to Jupiter. From the very accurate observations of Dr. Bradley, it appears, that the light of the sun passes from that luminary to the earth in eight minutes and twelve seconds.

The next property of light to which it is proper to advert is, that it is detached from every luminous or visible body in all directions, and constantly moves in right lines. It is evident that the particles of light move continually in right lines, since they will not pass through a bended tube; and since if a beam of light is in part intercepted by any intervening body, the shadow of that body will be bounded by right lines passing from the luminous body, and meeting the lines which terminate the interceding body. This being granted, it is obvious, that the rays of light must be emitted from luminous bodies in every direction; since, whatever may be the distance at which a spectator is placed from any visible object, every point of the surface which is turned towards him is visible to him, which could not be upon any other principle.

The rarity of light, and the minuteness of its particles, are not less remarkable than its velocity. If indeed the Creator had not formed its particles infinitely small, their excessive velocity would be destructive in the highest degree. It was demonstrated, that light moves about two millions of times as fast as a cannon-ball. The force with which moving bodies strike, is in proportion to their masses multiplied by their velocities; and consequently, if the particles of light were equal in bulk to the two-millionth part of a grain of sand, we should be no more able to endure their impulse than that of sand shot point-blank from the mouth of a cannon. The minuteness of the rays of light is also demonstrable from the facility with which they penetrate glass, chrystal, and other solid bodies, which have their pores in a rectilinear direction, and that without the smallest diminution of their velocity, as well as from the circumstance of their not being able to remove the smallest particle of microscopic dust or matter which they encounter in their progress. A further proof might be added, that if a candle is lighted, and there is no obstacle to obstruct its rays, it will fill the whole space within two miles around it almost instantaneously, and before it has lost the least sensible part of its substance.

To the velocity with which the particles of light are known to move, may in a great measure be attributed the extreme rarity and tenuity of that fluid. It is a well-known fact, that the effect of light upon the eye is not instantaneous, but continues for a considerable time. Now we can scarcely conceive a more minute division of time than the 150th part of a second. If, therefore, one lucid point of the sun's surface emits 150 particles of light in one second, we may conclude that this will be sufficient to afford light to the eye without any seeming intermission; and yet, such is the velocity with which light proceeds, that still these particles will be at least 1000 miles distant from each other. If it was not indeed for this extreme tenuity of the fluid, it would be impossible that the particles should pass, as we know they do, in all directions without interfering with each other. In all probability the splendour of all visible objects may be in proportion to the greater or less number of particles which are emitted or reflected from their surface in a given space of time; and if we even suppose 300 particles emitted successively from the sun's surface in a single second, still these particles will follow each other at the immense distance of above 500 miles.

Of the reflection of light, or *catoptrics*. It has been already intimated, that the rays of light which proceed from any luminous body move always in straight lines, unless this direction or motion is changed by certain circumstances; and these are reflection, refraction, and inflection.

The great law of reflection, and which serves to explain all its phenomena, is this, that the angle of reflection is always equal to the angle of incidence. It has been already intimated, that by the angle of incidence is meant the angle made by a ray of light with a perpendicular to the reflecting surface at the point where the ray falls; and by the angle of reflection, the angle which the ray makes with the same perpendicular on the other side.

A ray of light falling perpendicularly on a plane surface, is reflected back exactly in the same direction in which it came to the reflecting surface: rays falling obliquely observe the general law of reflection, and their angle of reflection is exactly equal to the angle of incidence. In Plate I. Optics, fig. 1., *fc* is a ray of light falling perpendicularly on the plane surface *ab*, and it is reflected back exactly in the same direction; *ec* is a ray falling obliquely on the surface at *c*, and it is reflected in the direction *cd*, making the angle of reflection *cd* P exactly equal to the angle of incidence *ec*P, as may be seen by inspection of the figure.

Parallel rays falling obliquely on a plane reflecting surface are reflected parallel, converging rays are reflected with the same degree of convergence, and diverging rays equally diverging. In other words, plane surfaces or mirrors make no change in the previous disposition of the rays of light.

A mirror is a body, the surface of which is polished to such a degree as to reflect most copiously the rays of light. Figs. 1, 2, 3, are plane mirrors: in fig. 2. the rays *db* and *ca*, which are parallel, after having reached the surface *ab* are reflected, the one towards *h* and the other towards *k*, and in both instances the angle of reflection is evidently equal to the angle of incidence.

The rays *db* and *ca* (fig. 3.) are convergent, and without the interposition of the mirror would unite in the point E; but being reflected, they unite in the opposite point F: the angle of reflection with respect to each being still equal to the angle of incidence, as may be seen by drawing perpendiculars to the points *a* and *b*.

The rays *db* and *ca* (fig. 4.) are on the contrary divergent, and after reflection towards *h* and *k*, preserve exactly the same distance from each other as they would have had if they had proceeded without interruption towards F and E, the angle of reflection being with respect to each ray still exactly equal to the angle of incidence.

Thus it is that plane surfaces reflect the rays of light; but the effects are materially different when the surfaces are convex or concave, though the same law still obtains with respect to these. From a convex surface, parallel rays, when reflected, are made to diverge; convergent rays are reflected less convergent, or are even made to diverge in proportion to the curvature of the surface compared with their degree of convergence; and divergent rays are rendered more divergent. Thus it is the nature of convex surfaces to scatter or disperse the rays of light, and in every instance to impede their convergence. From a concave surface, on the contrary, parallel rays when reflected are made to converge; converging rays are rendered more convergent; and diverging rays are made less divergent, or even in certain cases may be made to converge.

To understand this part of the subject, it is necessary to be aware, that all curvilinear surfaces are composed of right lines infinitely short, or points; and the reader will recollect, that only those rays which fall perpendicularly on a reflecting surface are reflected back in the same direction. All curves are arches or segments of circles: if therefore any curvilinear or spherical surface is presented to a number of parallel rays, it is evident that only that ray which strikes the spherical surface in such a direction that it would proceed in a right line to the centre of that circle, of which the reflecting surface is an arch or segment, can be said to fall perpendicularly upon it, of which the reader may convince himself by drawing a straight line with a ruler at any point of a given circle or curve. All the rest of the parallel rays, therefore, falling on the spherical surface, will fall obliquely upon it, and will consequently be subject to the general law of reflection, and the angle of their reflection will be equal to the angle of their incidence.

Perhaps the subject will be rendered still plainer, if, pursuing the idea thrown out in the preceding paragraph, that all curves are formed of a number of straight lines infinitely short, and inclining to each other like the stones in the arch of a bridge, we present to the reader the figures 5, 6, 7; which may be imagined so many mirrors bent or inclined in the form which is represented in the plate. The rays *ab* and *cd* (fig. 5.), which are parallel, are from their different points of incidence rendered divergent in *h* and *e*; the angle of reflection with respect to each being equal to the angle of incidence.

In fig. 6. the rays *ab* and *cd* are convergent, and would, without the interposition of the reflecting surface *bd*, unite in *m*; but according to the same principle, they now proceed to unite in *l*, which is more distant from the reflecting surface than the point *m*; and it is evident, that if the curvature of the two branches of the reflecting surface *b* and *d* was greater, they might be reflected parallel, or even divergent. In the same manner, as in fig. 7., the rays *ab* and *cd*, which, without the interposition of the convex surface *bd*, would diverge but very little at *m*, become after reflection much more divergent at *l*; and the angles of reflection will be found in all these cases exactly equal to the angles of incidence, if measured from the reflecting surface produced or lengthened, as at *fg* and *ik*.

Let now fig. 8 represent a concave mirror formed upon the same principles as those which we have been examining of the convex kind. The rays *ab*, *cd*, which were parallel before reflection, and which make their angles of reflection equal to their angles of incidence (measured for convenience in this figure from the reflecting surface produced), become evidently convergent at the point *l*; upon the same principles in fig. 9. the converging rays *ab* and *cd*, which would not have united before they reached the point *m*, are now after reflection united at *l*, which is much nearer the reflecting surface. In fine, the divergent rays *ab* and *cd* in fig. 10., which would have become more divergent at *m*, had they not been intercepted by the reflecting surface, become convergent after reflection, and are found actually to unite at *o*.

Mirrors are formed either of metal, or of glass plated behind with an amalgam of mercury and tin. The latter are most in common use; but they are improper for optical instruments, such as telescopes, &c. because they commonly present two images of the same object, the one vivid and the other faint, as may be perceived by placing the flame of a wax-taper before a common looking-glass. The reason of this double image is, that a part of the rays are immediately reflected from the anterior surface of the glass, and thus form the faint image; while the greatest part of the rays penetrating the glass are reflected by the amalgam, and form the vivid image.

From the principles laid down, most of the phenomena of reflection may be explained. In plane mirrors, the image appears of its natural size, and at the same distance behind the glass as the object is before it. To understand perfectly the reason of this, it will be necessary to advert to the subject of vision, as formerly explained. It will be remembered, that by the spherical form of the eye, and particularly by means of the chrystalline humour which is placed in the middle of it, the rays of light are converged; and those from the extreme points of the object cross each other, so as to form an inverted image on that part of the optic nerve which is called the retina. The apparent magnitude of objects will consequently depend upon the size of the inverted image, or, in other words, upon the angle which the rays of light form, by entering the eye from the extremities of any object.

As therefore the angle of reflection is always equal to the angle of incidence, it will be evident on the inspection of fig. 11. that the converging rays K*m*, L*n*, proceeding from the extremities of the object KL, and falling on the mirror *ab*, are reflected to the eye at *e* with the same degree of convergence, and consequently will cause the image *kl* to be seen under an angle equal to that under which the object itself would have been seen from the point *i* without the interposition of the mirror. The image appears also at a distance behind the mirror equal to that at which the object stands before it. For it must be remembered, that objects are rendered visible to our eyes not by a single ray proceeding from every point of an object, but that in fact pencils or aggregates of divergent rays proceed from every point of all visible objects, which rays are again, by the mechanism of the eye, converged to as many points on all those parts of the retina where the image is depicted. The point from which the rays diverge is called the focus of divergent rays; and the point behind a reflecting surface from which they appear to diverge, is called the virtual focus. As therefore the angle of reflection is exactly equal to the angle of incidence, it is evident that the virtual focus will be at the same distance behind the mirror as the real focus is at before it. Thus, in fig. 12., the diverging rays *ch* will after reflection appear to diverge from the point *g* which is behind the mirror *ab*, and that point for the reasons assigned (viz. no alteration being made in the disposition of the rays but only in the direction) will be at an equal distance behind the mirror with the luminous point *c* before it.

As every part of the image appears at a distance behind the mirror equal to that at which the object stands before it, and as the object KL (fig. 11.) is inclined or out of the vertical position, the image *kl* appears also inclined. Hence it is evident, that to exhibit objects as they are without any degree of distortion, looking-glasses should be always hung in a vertical position, that is, at right angles with the floor of the apartment.

It is clear, however, from what has preceded, that the case must be very different with those mirrors, the surfaces of which are spherical, whether convex or concave. Of the former it has been shewn that their property is to scatter and disperse the rays of light, to render those divergent which were parallel, to diminish the convergence of converging rays, and to augment the divergence of those which diverged before. The first obvious effect of these mirrors, therefore, must be to exhibit the image of the object which is opposed to them smaller than it is in reality. For the angle under which the rays strike the eye of the observer, must necessarily be smaller in proportion to the convexity of the mirror. Suppose, for instance, the object CD (fig. 13.) placed before the convex mirror *ab*; the two rays C*c* and D*d*, which proceed from the extremities of the object, and which, without the interposition of the mirror, would converge at *f*, are reflected less convergent, and unite at *i*, forming an angle much more acute than they would otherwise have done. The consequence, therefore, of the visual angle being so much more acute, is, that the image *gh* is proportionably smaller than the object itself.

The second effect of this dispersion of the rays is, that the image appears at a less distance behind the glass than it would have done in a plane mirror. To understand this effect, it is necessary again to advert to a principle of optics which has been just stated, viz. that objects are rendered visible not by a single ray of light proceeding from every point of the object, but that from every minute point of the surface of every visible object pencils of divergent rays proceed, which are again converged on the retina of the spectator's eye.

Suppose then G (fig. 14) a luminous point of any visible object, from which a pencil of divergent rays proceed, and fall upon the convex mirror *ab:* these rays, agreeably to the nature of these mirrors, are reflected more divergent, and have their fictitious point of re-union (or virtual focus) *g* much nearer to the eye and to the surface of the mirror, than they would otherwise have. The image, therefore, as may be seen in the figure, instead of being at a distance behind the mirror equal to the distance at which the object stands before it (as would be the case in a plane mirror), will appear at a smaller distance, and this distance will always be diminished in proportion to the convexity of the mirror.

For the same reasons an object of a certain size, placed either perpendicularly or obliquely before a convex mirror, will necessarily appear curved or bent, because the different points of the object are not at equal distances from the surface of the mirror. All these effects will be very apparent from inspecting one of those small glass globes, lined with the common amalgam for making looking-glasses, which are sometimes suspended in old-fashioned apartments. In these the company seated in the room or round the table, are represented by very minute images, which appear not at a certain distance behind as in plane looking-glasses, but very near the surface of the mirror, and always in some degree curved or distorted.

The effects and phenomena of concave mirrors will obviously, from what has been said, be the direct contrary to those of the convex kind. The surface of concave mirrors is generally spherical (or in in the form of a globe); though that is not always the most convenient form for optical purposes, but it is that which is least difficult to the workmen.

The general effect of concave mirrors is, we have already seen, to render the rays more convergent. The point in which the converged rays unite is called the focus of converging rays; but this focus cannot be the same for all the rays incident on a concave surface. The parallel rays *ab*, *de* (fig. 15.), are converged by the mirror at the point F, which is distant from the mirror one-fourth part of the diameter of that circle, of which the mirror is a part or section; and this is the point which is called the focus of parallel rays, and it is the real or principal focus of the mirror. The converging rays *fg*, *hi*, are reflected upon the same principles more convergent, and unite at the point K, nearer to the surface of the mirror than the principal focus. In fine, the divergent rays R*m* and R*o*, which proceed from the point R, beyond the principal focus, unite at the point P. But if the point of divergence was nearer the mirror than the principal focus, as for instance at K, they would still be reflected divergent, and would proceed one towards *f* and the other towards *h*.

Plane and convex mirrors exhibit, as has been already mentioned, the image behind the glass or mirror, and in a situation conformable to that of the object; but concave mirrors shew the image behind when the object is placed between the principal focus and the mirror, and then the image is larger than the object. Let AB (fig. 16.) be the object placed before the concave mirror EF, and nearer to the mirror than its principal focus. The two pencils of rays A*e*, B*f*, which proceed from the extremities of the object, and which, without the interposition of the mirror, would converge at *d*, are reflected more converging, and unite at D; and making an angle greater or more obtuse than they would otherwise have done, the image *ab* is consequently greater than the object.

This image too appears at a greater distance behind the mirror than the object is at before it. The reason of this will appear, if we suppose A (fig. 17.) a point of any object placed nearer to the mirror than the principal focus F, whence a pencil of divergent rays proceed, and falling on the mirror, are (according to the principles before laid down) reflected less divergent, and consequently have their virtual or imaginary focus at a greater distance, than if the object had been placed before a plane mirror.

If, on the contrary, the object is placed farther from the mirror than the principal focus, as for instance at *e*, the rays *eb*, *ed*, being only moderately divergent when they come in contact with the mirror, are reflected convergent, and will represent at E an image of the object. If the eye, therefore, is withdrawn to a sufficient distance (to *o* for example) for the rays to cross each other, it will perceive the image suspended in the air at E between the mirror and itself. The reason of this depends upon what has been already stated. Every object is rendered visible to us by pencils of divergent rays from every point of that object; it therefore ceases to be visible if these rays are converged to a point, and this happens when the object is not nearer to the mirror than the principal focus. To render, therefore, an object thus situated visible, it is necessary that the eye should recede so far beyond the place of the image E, as to allow the rays to cross each other, and meet the eye in a state of divergence.

The image is in this case always inverted. Such is the image *ba* of the object AB (fig. 18.). From this property of the concave reflector to form the image of an object, in these cases, before the reflector, many deceptions have been produced, to the great surprise of the ignorant spectator. He is made to see a bottle half-full of water inverted in the air without losing a drop of its contents; as he advances into a room, he is tempted to exclaim with Macbeth, " Is this a dagger that I see before me?" and when he attempts to grasp it, it vanishes into the air.

A variety of similar appearances may be represented, which are all produced by means of a concave mirror, having an object before it strongly illuminated, care being taken that only the rays of light reflected from the object shall fall upon the concave reflector, placed in such a manner that the image shall be in the middle of the adjoining room; or, if in the same room with the object and reflector, a screen must be placed so as to prevent the spectator from discovering them. A hole is then made in the partition between the two rooms, or in the screen, through which the rays pass by which the image is formed. The spectator then, when he casts his eyes upon the partition of the screen, will, in certain situations, receive the rays coming through this small aperture. He will see the image formed in the air; he will have no idea, if not previously acquainted with optics, of the nature of the deception; and may either be amused, according to the inclination of his friends, with tempting fruit, or be terrified at the sight of a ghastly apparition.

Since it is the property of a concave mirror to cause those rays which proceed in a parallel direction to its surface, to converge to a focus; and since the solar rays, from the immense distance of that body, may be considered as parallel; concave mirrors prove very useful burning-glasses: and the focus of parallel rays, or principal focus, is their focus or burning-point.

Cylindrical mirrors, such as that represented in fig. 19. are employed more for the purpose of amusement than of philosophy. They are called mixed mirrors, because they produce at the same instant the effects of plain and of convex mirrors. Suppose, for instance, GF (fig. 20.) to be the height of such a mirror, and AE an object placed before or rather below it; all the rays which proceed from the points A, B, C, D, E, falling on the surface GF of the mirror, and reflected to the eye at O, will represent the images of these different points at *a*, *b*, *c*, *d*, *e*, as they would be represented in a plane mirror; and with respect to these, the dimensions of the object will not be altered in the corresponding image. But since the mirror is also curved, if we suppose the space *q*, *t*, *y*, (fig. 21.) to represent a part of its circumference, the rays A*q*, L*r*, M*s*, N*t*, O*x*, P*z*, F*y*, being reflected to the eye at Z, will exhibit all these points A, L, M, N, &c. within the space *af*; which will in this direction diminish considerably the dimensions of the image, according to the principles already explained in treating of the convex mirror, viz. by diminishing the convergence of rays, and consequently reducing the size of the image in proportion to the convexity. In the cylindrical mirror, it must be observed, that it is in the breadth only that this diminution takes place. The same will take place with respect to all the points of the object which are visible within the lines BQG, CRH, DTI, ESK, concentric to the surface of the mirror. These parts must therefore be very much extended in the drawing or design, if a perfect image is to be represented in the mirror. Distorted drawings of this kind are common in the shops of the opticians, which, on a cylindrical mirror being placed on the board or drawing, display perfect figures. The principle of these will, however, be very easily understood from what has been now stated.

The conical mirror is represented in fig. 22, and this is also considered as a mixed mirror; for, as well as the cylindrical, it produces at once the effects of a convex and a plane mirror. Suppose, for instance, the angle CKF (fig. 23.) to represent this mirror, and the lines CK, FK, two of the right lines which compose it. These two lines would then answer to two plane mirrors inclined towards each other: and the rays proceeding from the points ABC, falling on the surface at *g*, *h*, *i*, and reflected towards the eye at O, would represent these points as if at the base of the mirror in the opposite order *a*, *b*, *c*; and the same observation will apply to the points D, E, F, which are represented at *d*, *e*, *f*, as well as all those which are in the circles AHD, BIE, CGF. But as there do not proceed from each point simple rays of light, but pencils of rays, they are modified in this mirror upon the same principles as in the convex mirror; and consequently the image will appear smaller than the object, and nearer to the eye, than in the plane mirror.

Hence it will be evident, that we may see in the centre the image of whatever is painted on the exterior circumference AHD, and the extremities of the image will be formed from the interior circle CGF; and as the curvature or convexity of the mirror is greater towards the apex or point of the cone, it follows, that that which is the most extended in the object will be the most compressed or concentrated in the image. Thus the dark part of the board (fig. 24.) is intended to represent in the mirror an ace of spades; and the points *a*, *b*, *c*, *d*, *e*, *f*, *g*, &c. which are nearest to the mirror, form the outer circumference of the image; and the points 1, 2, 3, 4, 5, 6, 7, 8, of the external circumference of the board, unite in the centre of the image at an almost imperceptible point.

Of the refraction of light, or *dioptrics*. It has been proved that light, like every known substance, is subject to the laws of attraction; it has been intimated too, that even its propensity to move in a direct line is, in certain cases, overcome by this superior influence; and that the direction of the rays of light is changed in passing from one medium to another. The space in which a ray of light moves is called a medium; whether pure space, air, water, glass, or any other transparent substance; and when a ray is bent out of its natural course in passing from one medium to another, it is said to be refracted or broken, probably from the broken appearance which a staff, &c. exhibits when part of it is immersed in water.

There are two circumstances essential to refraction: 1st, That the rays of light shall pass out of one medium into another of a different density, or of a greater or less degree of resistance. 2dly, That they pass in an oblique direction.

The denser the refracting medium, or that into which the ray passes, is, the greater will be its refracting power; and of two refracting mediums of the same density, that which is of an oily or inflammable nature will have a greater refracting power than the other.

The angle of refraction depends on the obliquity of the rays falling on the refracting surface being such always, that the sine of the incident angle is to the sine of the refracted angle in a given proportion.

The incident angle is the angle made by a ray of light, and a line drawn perpendicular to the refracting surface, at the point where the light enters the surface; and the refracted angle is the angle made by the ray in the refracting medium with the same perpendicular produced. The sine of the angle is a line which serves to measure the angle, being drawn from a point in one leg perpendicular to the other.

In passing from a rare into a dense medium, or from one dense medium into a denser medium, a ray of light is refracted towards the perpendicular, that is, so that the angle of refraction shall be less than the angle of incidence; on the contrary, in passing from a dense medium into a rare medium, or from one rare medium into a rarer, a ray of light is refracted from the perpendicular. Thus, in passing from empty space into air, or any other medium whatever, the ray is bent towards the perpendicular; and in passing from any other medium into pure space, it is bent the contrary way, that is, from the perpendicular; the same effects will take place in passing from air into glass, and from glass into air, &c.

To render this perfectly clear, let us have recourse to fig. 25. If a ray of light *p*G passes from air to water, in the direction *p*G, perpendicular to the plane D*d*, which separates the two mediums, it suffers no refraction, because one of the essentials is wanting to that effect, viz. the obliquity of the incidence.

But if a ray AG passes obliquely from air into water, instead of continuing its course in the direct line GB, it takes the direction G*a*, and approaches the perpendicular *p*P, in such a manner that the angle of refraction PG*a* is less than its angle of incidence *p*GA.

If the ray came in a more oblique direction, the refraction would be still greater; so that in all cases where the mediums are the same, the angle of refraction will always be found to bear a regular and constant proportion to the angle of incidence; or, to speak in technical language, the sine of incidence is to the sine of refraction in a given ratio, and this ratio is discovered by experience. Thus, when a ray passes out of air into water, the ratio is as 4 to 3.

out of water into air, as 3 to 4.
air into glass, as 3 to 2.
glass into air, as 2 to 3.
air into diamond, as 5 to 2.
diamond into air, as 2 to 5.

The refraction of light is attributed by sir Isaac Newton to the principle of attraction; and perhaps one of the most satisfactory proofs of this theory is the known fact, that the change in the direction of the ray commences, not when it comes in contact with the refracting medium, but a little before it reaches the surface, and the incurvation augments in proportion as it approaches this medium. Indeed no principle will account for the phenomenon of light passing more easily, that is, more directly, through a dense than through a rare medium, but that of attraction; since it is found by universal experience, that the attraction of all bodies is in proportion to their densities.

In passing from a dense into a rare medium, however, there is a certain degree of obliquity at which the refraction is changed into reflection. In other words, a ray of light will not pass out of a dense into a rare medium, if the angle of incidence exceeds a certain limit, but will be reflected back. Thus a ray of light will not pass out of glass into air, if the angle of incidence exceeds 40° 11; or out of glass into water, if the angle of incidence exceeds 59° 20.

As the rays of light, in passing from a dense medium to a rarer, are refracted from the perpendicular, in fact are bent or inclined towards the eye of the spectator, who looks at an object in the denser medium while standing at its side, the reason will be clear why the bottom of a river appears to us nearer than it really is. If the spectator stands on a bank just about the level of the water, it is about one-third deeper than it appears; and why an oar, partly in and partly out of the water, seems broken. Let Q*no* (fig. 26.) represent an oar, the part *n*Q being out of, and the part *no* being in, the water; the rays diverging from *o* will appear to diverge from *b* nearer to the surface of the water, and every point in *no* will be found nearer to the surface than its real place, and the part *no* will appear to make an angle with the part Q*n*. On this account also, a fish in the water appears much nearer the surface than it actually is; and a skilful marksman, in shooting at it, will aim considerably below the place which it seems to occupy.

On the same principle a common experiment is explained. Put a shilling into a bason, and walk back from it till the shilling is just obscured by the side of the bason; then by pouring water into the bason, the shilling instantly appears; for by what has been said above, the object, being now in a denser medium, is made to appear nearer to its surface.

As the refraction must in all cases depend on the obliquity of the ray, that part of any body which is most immersed will seem to be most materially altered by the refraction. When, however, the object extends to no great depth in the water, the figure is not materially distorted; but if the object is of a considerable size, or extends to a great depth, those rays which proceed from the more distant extremities come in a more oblique direction on their emergence into the air, and they consequently suffer a greater refraction than the rest. Thus a straight leaden pipe appears near the bottom of a deep water to be curved, and a flat bason seems deeper in the middle than near the sides.

To these laws of refraction is to be attributed the difference between the real and the apparent rising of the sun, moon, and stars, above the horizon. The horizontal refraction is something more than half a degree, whence the sun and moon appear above the horizon when they are entirely below it. From the horizon the refraction continually decreases to the zenith. Refraction is increased by the density of the air, and consequently it is greater in cold countries than in hot; and it is also affected by the degree of cold or heat in the same country.

Parallel rays, if refracted, preserve their parallel direction both in entering and in passing out of a refracting medium, provided the two surfaces of the refracting medium are parallel. The two rays, EA, EA, (fig. 27.) after refraction, while they approach the perpendiculars *pp*, continue parallel as before, the reason of which is evident on the principles already established; for the ray AC, (Pl. II. fig 3.) on coming in contact with the surface of the refracting medium EF, does not continue its course in the straight line C*b*, but being refracted at the point of contact C, it approaches the perpendicular P*p*, and comes out at *a*.

After coming out of the refracting medium, if we suppose the surface GH parallel to EF, it ought to proceed to B, having deviated from the perpendicular in the same degree in which it approached it on its first refraction; and thus it continues parallel to the line CB, which is that in which it would have proceeded if it had not been intercepted by the medium.

This parallelism cannot subsist if the two surfaces KI, HI, (fig. 4.) are inclined, as in the figure; because the ray entering at *a*, and emerging at *b*, the object A will be seen from the point B at *e*, which is out of its true place.

Converging rays become less convergent in passing from a rare to a denser medium, as from air into water; and on the contrary, their convergence is augmented by passing from a dense to a rarer medium, as from water into air. (See fig. 1.) In the same manner, diverging rays become less divergent in passing out of a rare medium into one which is denser, and their divergence is increased by passing out of a dense into a rarer medium. (See fig. 2.) This fact is a necessary consequence of the general law of refraction: but it will satisfactorily explain why an object under water appears larger to an eye above the surface than it really is, and why all objects appear magnified seen through a mist; for in all these cases, the converging rays, by which we see the extreme points of the object, and which during their passage through the water, &c. were refracted towards the perpendicular, on their emergence into the air are made more suddenly to converge, and consequently the visual angle is rendered more obtuse.

It is evident, that when parallel rays fall upon a spherical surface, that ray only which penetrates to the centre or axis will proceed in a direct course; for all the rest must necessarily make an angle more or less obtuse, in proportion to their distance from the centre; they are therefore rendered convergent or divergent according to the nature of the medium on which they are incident. If they fall on the convex surface of a medium denser than that which they leave, as in passing from air into glass, they will converge, as may be seen in Plate II. fig. 5. where that phenomenon is represented; for the parallel rays, *hi*, *fg*, (fig. 10.) falling in an oblique direction on the refracting medium terminated by the convex surface E*ig*, they will be refracted, and will each respectively approach the perpendiculars *i*C, or *g*C, and will consequently have a tendency to unite towards the axis AB.

It is however proper to remark, that the point at which they join the axis AB will be distant from the surface of the refracting medium, in proportion as the point on which they fall on the convex surface is distant from that axis; because the more distant that point is, the more oblique is the incidence of the ray. Thus the ray *hi* joins the axis at *k*; but the ray *fg* does not join the axis till it arrives at D.

Rays already convergent, falling on the convex surface of a dense medium, will be acted upon differently according to circumstances.

If their convergence is exactly proportioned to the convexity of the surface, they will not suffer any refraction; (see fig. 6.) because in that case one of the essentials is wanting to refraction, viz. the obliquity of the incidence; and each ray proceeds in a direct line to the centre of that circle, of which the convex surface is an arch or segment.

For instance, the rays *ef* and *dh*, (fig. 11.) which tend to unite at C, the centre of the convex surface, may be considered as perpendicular, being the radii of the circle.

If the rays have a tendency to converge before they reach the centre of the convexity, they will then be rendered less convergent for instead of converging to a point at *b* (fig. 7.), they will converge at B. The reason of this is evident; for the ray *ih* (fig. 11.) which, if not intercepted, would meet the axis at *k*, nearer the surface of the refracting medium than the centre of convexity C, being refracted towards the perpendicular or radius *d*C, meets the axis only at *o*.

If, on the contrary, the rays have a tendency to converge beyond the centre of the convexity, they will then, by the law of refraction, be rendered still more convergent, as in fig. 8; where their point of union, if not intercepted, would be *c*; but where, by the influence of the refraction, they are found to converge at C. For the ray *gh*, (fig. 11.) the tendency of which is towards *l*, is refracted towards the perpendicular *d*C, and joins the axis at *p*.

If diverging rays fall on the convex surface of a denser medium, they are always rendered less divergent, as in fig. 9.; and they may be rendered parallel, or even convergent, according to the degree of divergence compared with the convexity of the refracting surface, on the principles already explained.

If rays pass from a dense to a rarer medium, the surface of the dense medium being convex, in this case parallel rays become convergent; for the parallel rays *de*, *gi*, (fig. 12.) when they reach the convex surface *e*D*i*, instead of continuing their direct course, are refracted from the perpendiculars *a*C, *b*C, and converge at *k*.

Converging rays are also rendered more convergent. Thus the rays *le*, *ui*, which without any change in the medium, would have proceeded in the direction *m* and *o*, in consequence of the refraction which they suffer, and which bends them from the perpendiculars *a*C, *b*C, unite at *p*.

Diverging rays, if they proceed from the point C, the centre of convexity, suffer no refraction; because, for the reasons already assigned, they may be considered as perpendicular to the refracting surface, and consequently they are deficient in one of the causes of refraction, the obliquity of incidence.

If they proceed from a point which is nearer to the surface than the centre of convexity, such as *r*, they will be refracted from the perpendiculars *a*C, *b*C, and will be rendered more divergent towards *x* and *y*.

If, on the contrary, the diverging rays come from a point such as *q*, beyond the centre of convexity, they will be rendered less divergent; for instead of going towards *z* and *z*, they will be refracted from the perpendiculars *a*C, *b*C, towards *f* and *h*.

When rays pass from a rare into a dense medium, and the surface of the dense medium is concave, then parallel rays are rendered divergent, as in Plate II. fig. 13.; for the parallel rays *ab*, *de*, (fig. 17.) are refracted towards the perpendiculars *f*C and *g*C, and are consequently divergent.

Converging rays falling on the same concave surface will be rendered less convergent, as in fig. 14. For the rays *ab*, *de*, (fig. 18.) which would have converged at O if their progress had not been intercepted, will be refracted towards the perpendiculars *f*C and *g*C, and will unite only at *i*. If the convergence was less, they might by the refraction be rendered parallel, or even divergent.

Diverging rays proceeding from the centre of concavity will not suffer any refraction, for the reasons already assigned.

If, however, diverging rays proceed from any point nearer the refracting surface than the centre of concavity, they will be rendered less divergent, as in fig. 15. For the two diverging rays *kb* and *ke* (fig. 19.), instead of proceeding to *d* and *h*, are refracted towards the perpendiculars *f*C and *g*C.

If, on the contrary, which is the most general case, the diverging rays proceed from a point more distant from the surface than the centre of concavity, their divergence will be increased, as in fig. 16. For the diverging rays *lb* and *le* (fig. 19.), which tend towards *m* and *n*, are refracted towards the perpendiculars *f*C and *g*C, and become more divergent than they would otherwise have been.

When rays pass from a dense into a rarer medium, and the dense medium is terminated by a concave surface, then

Parallel rays become divergent; for the parallel rays *de*, *gi*, (fig. 20.) when they reach the concave surface *e*D*i*, instead of continuing their course in the direct lines towards *f* and *h*, proceed towards *m* and *p*, being refracted from the perpendiculars C*a*, C*b*, and are consequently divergent.

Converging rays, if their point of convergence is precisely at C, the centre of the concavity eDi, will not suffer any refraction, because they are perpendiculars, as already explained, therefore have no obliquity of incidence. If, on the other hand, the rays tend to a point, such as n, nearer to the surface than the centre of the concavity C, then they are rendered more convergent; for the rays qe, ri, which naturally tend to that point, are refracted from the perpendiculars Ce, Ci, and converge at o, nearer the concave surface.

Lastly, if the converging rays tend to a point l, which is beyond the centre C, they are rendered less convergent. For the rays se, ti, which would naturally unite at that point, are refracted from the perpendiculars Ce, Ci, and unite at k, which is more distant still.

Diverging rays in the same circumstances are rendered more divergent. For the rays Ee, Ei, diverging from the point E, instead of proceeding towards a and x, are refracted from the perpendiculars, and are directed towards y and z.

From the property which all spherical convex surfaces have, of rendering parallel rays passing out of a rarer medium convergent, glasses made in this form are very commonly used as burning-glasses; and as the sun's rays, proceeding from so vast a distance, may be considered as parallel, the focus of parallel rays will of course be their burning-point.

A lens is a transparent body of a different density from the surrounding medium, and terminated by two surfaces, either both spherical, or the one plane and the other spherical, whether convex or concave. They are therefore generally distinguished by their forms, and are called plano-convex or plano-concave, or double convex or double concave; a lens which has one side convex and the other concave, is called a meniscus, or concave-convex lens. See Plate II. fig. 21.

It is evident, that in lenses there may be almost an infinite variety with respect to the degree of convexity or concavity; for every convex surface is to be considered as the segment of a circle, the diameter and radius of which may vary to almost an infinite extent. Hence, when opticians speak of the length of the radius as applied to a lens, as for instance, when they say its radius is 3 or 6 inches, they mean that the convex surface of the glass is the part of a circle, the radius of which, or half the diameter, is 3 or 6 inches.

The axis of a lens is a straight line drawn through the centre of its spherical surface; and as the spherical sides of every lens are arches of circles, the axis of the lens would pass exactly through the centre of that circle, of which its sides are arches or segments.

From what has been already stated, it is obvious that the certain effect of a convex lens must be to render parallel rays convergent; to augment the convergence of converging rays; to diminish in like manner the divergence of diverging rays, and in some cases to make them parallel or even convergent, according to the degree of divergence compared with the convexity of the lens. In what is called a double-convex lens, this effect will be increased in a duplicate proportion, since both surfaces will act in the same manner upon the rays; and since it has been proved, that parallel or convergent rays have their convergence equally augmented by being incident on the convex surface of a dense, or the concave surface of a rare medium. These glasses then must necessarily have the effect of magnifying glasses, since by the convergence of the rays the visual angle is rendered more obtuse, and consequently the image which is depicted on the retina must be proportionably larger.

The focus of those rays which come in a parallel direction to the glass, is called the focus of parallel rays, or principal focus. In a plano-convex glass this focus is at the length of the diameter of that circle, of which the convex surface is a segment; and in a double-convex lens, or one which is convex on both sides, the focus is as the distance of the radius, or half the diameter, of the circle of which the lens is a segment. This focus therefore is easily found upon mathematical principles. It may also be found, though not with equal exactness, by holding a sheet of paper before the glass when exposed to the rays of the sun, and observing the distance of the paper from the glass when the luminous spot on the paper is very small, and when it begins to burn; or when the focal length does not exceed three feet, the focus may be found by holding the lens at such a distance from the wall opposite a window-sash, that the image of the sash may appear distinct upon the wall.

From this property in convex lenses, of rendering all rays in some degree convergent which fall upon their surfaces, it is evident that in all such cases there must be a point, which in general is at the focus, where pencils of rays proceeding from the extreme point of any object must first unite and then cross each other; and consequently an inverted image of the object will be exhibited at any distance beyond that point. This may be elucidated by a very easy experiment, viz. by holding a common reading or magnifying glass between a candle and a sheet of paper suspended on the wall, at a proper distance, when the image of the candle will appear on the paper inverted: and the reason of this is extremely clear; for it is evident that the upper pencils after refraction, are those which proceeded from the under part of the luminous body, and the under rays are those which come from its top. The position is therefore only inverted, and the image remains unimpaired.

From the same property, convex lenses will cause many rays to enter the eye which would otherwise have been scattered or dispersed, and therefore objects seen through them appear clearer and more splendid than when viewed by the naked eye. If, however, the glass is very thick (as in high magnifiers), some of the rays which enter it will be reflected or sent back, and consequently the brilliancy of the image will suffer some diminution.

A large object seen through a lens which is very convex will appear deformed; and this proceeds from the refraction not being equal at all points in such cases. The same cause operates also to render some parts of the image indistinct, while others are distinct and clear. Thus the extremities of the image seen through a lens of a very short focus are commonly confused and indistinct, because the refraction at the edges of the lens does not agree with that of the middle parts. The modes adopted for remedying these defects in optical glasses, will be hereafter explained.

The effects of a concave lens are directly opposite to those of the convex lens. In other words, by such a glass, parallel rays are rendered divergent, converging rays have their convergence diminished, and diverging rays have their divergence augmented, in proportion to the concavity of the lens. These glasses then exhibit objects smaller than they really are; for by causing the rays to diverge, or more properly by diminishing the convergence of the rays proceeding from the extreme points of the object, the visual angle is rendered more acute, and the image painted on the retina is smaller, than it would have been had these rays not been intercepted in their natural progress; and by the divergence of the rays the object is represented with less clearness than it would otherwise have had, since from this cause a less quantity of light enters the pupil of the eye. All concave lenses have a negative or virtual focus, which is a point corresponding with the divergence of parallel rays incident on the surface of the lens.

Light is, however, not so simple a substance as it may be supposed upon superficially considering its general effects; it is indeed found to consist of particles which are differently refrangible, that is, some of them may be refracted more than others in passing through certain mediums, whence they are supposed by philosophers to be different in size. The common optical instrument called a prism, is a triangular piece of glass, through which if a pencil or collection of rays is made to pass, it is found that the rays do not proceed parallel to each other on their emergence, but produce on an opposite wall, or any plane surface that receives them, an oblong spectrum, which is variously coloured, and it consequently follows that some of the rays or particles are more refrangible than others.

The spectrum thus formed is, perhaps, the most beautiful object which any of the experiments of philosophy presents to our view. The lower part, which consists of the least refrangible rays, is of a lively red; which, higher up, by insensible gradations, becomes an orange; the orange, in the same manner, is succeeded by a yellow; the yellow, by a green; the green, by a blue; after which follows a deep blue or indigo; and lastly, a faint violet.

Of Vision. There is not any part of the animal frame which displays in a more satisfactory manner to our reason, the wisdom and design of our Creator, than the eye. Its anatomical structure is however explained under the articles ANATOMY and PHYSIOLOGY. It is only necessary at present to consider it as an optical instrument. The external coat or case, which forms the globe of the eye, is at the back part strong and opake: the fore part is thin and transparent, so as to admit readily the rays of light; and it is therefore called the cornea, from its resemblance to polished horn. It incloses three pellucid matters called the humours, which are of different densities. That in the anterior part, immediately under the cornea, is called the aqueous humour; that immediately behind is the crystalline humour, which is a double-convex lens of great refracting power, and the rest of the eye is filled with a jelly-like substance called the vitreous humour. The iris, which is the coloured part of the eye, is an opaque membrane which is perforated by a small hole, the pupil, through which the rays of light must pass to the crystalline humour. The optic nerve enters at the under part, and is spread all over the interior surface, at the back of the eye, in the form of a fine net-work, and therefore is called the retina. The student of optics will see from this, that the eye is altogether calculated to act as a convex lens of strong refractive powers.

It has already been explained, that from every luminous point of a visible object, cones or pencils of light are emitted or reflected in every direction; but to produce vision, it is necessary that they should be concentrated or converged to such a point as to make a forcible impression on the retina. Thus from the luminous body A, Plate II. (fig. 22.) the rays *r*, *r*, *r*, are sent in various directions. Those which fall upon the transparent cornea CC, are there refracted in such a manner as to enter the pupil at *p*, and in passing the chrystalline lens or humour they suffer a second refraction, and are converged to a point or focus at the point *a* on the retina. Now it is evident, that if the rays could have passed the humours of the eye in their natural direction, that is, in the direction of the cone or pyramid CAC, they would have made upon the retina a very extensive but feeble impression, such as we know by experience could not produce distinct vision; to obviate this it is appointed by the all-wise Author of our existence, that by the force of the refraction which they suffer in the eye, they should form another cone opposed to the first at its base, and the apex of which is at *a*, and thus an impression sufficiently forcible to produce distinct vision is made on the retina.

In the preceding instance, the luminous body A was considered as a point; and what has been said of it will apply to every point of a visible object, which is capable of transmitting or reflecting to the eye a pencil or collection of rays. Thus we may easily suppose that from every part of the arrow O A B, (fig. 23.) cones or pencils of light may be transmitted; these, like all pencils or collections of rays, coming from a point, will diverge, and will fall upon the eye in some degree divergent, or in the form of cones or pyramids.

The pencil of rays OEIF will then paint the extremity O in the point I; the pencil BFME will also paint the extremity B in the point M; and since all the points between O and B are represented between I and M, of course IM will be the image of OB. Hence it is evident, that by means of this refraction there are certain points at which the rays of light, after passing the pupil, cross each other, and the image which is formed on the retina is consequently inverted.

Artificial eyes are sold by the opticians, in which all the humours are made of different kinds of glass, and may be separated at pleasure. At the back part, where the retina is supposed in the natural eye to receive the converged rays, is placed a piece of ground glass, where the image from the opposed object is rendered in an inverted position, as in a camera obscura. The same effect may be produced with a natural eye, and the nature of vision may be thus experimentally demonstrated: if a bullock's eye is taken fresh, the posterior coats dexterously removed even to the vitreous humour, and if a piece of white paper is then placed at the part, the image of any bright object which is placed before the eye will be seen distinctly painted on the paper, but in an inverted position.

If the humours of the eye, through age or weakness, have shrunk or decayed, the cornea will then be too flat; and the rays, not being sufficiently bent or refracted, arrive at the retina before they are united in a focus, and would meet, if not intercepted, in some place behind it, as in Plate II. fig. 25. They therefore do not make an impression sufficiently correct and forcible, but form an indistinct picture on the bottom of the eye, and exhibit the object in a confused and imperfect manner. This defect of the eye is therefore remedied by a double-convex lens, such as the common spectacle-glasses, which, by causing the rays to converge sooner than they otherwise would, afford that aid to this defect of nature which the circumstances of the case may require; the convexity of the glass being always proportioned, by one who is capable of directing in the choice of spectacles, to the deficiency in vision.

If, on the contrary, the cornea is too convex, the pencils of rays will unite in their foci before their arrival at the retina, as in fig. 26, and the image will also be indistinct. This defect is remedied by concave glasses, which cause the rays to diverge; and consequently, by being properly adapted to the case, will enable the eye to form the image in its proper place.

The rays of light being emitted or reflected from a visible object in all directions, it must be plain that some of them from every part of it must reach the eye. Thus the object AB (Plate II. fig. 28) is visible to an eye in any part where the rays *Aa*, *Ab*, *Ac*, *Ad*, *Ae*, B*a*, B*b*, B*c*, B*d*, B*e*, C*a*, C*b*, C*c*, C*d*, and C*e*, can come. But though rays are reflected from every point of the object to every part of the circumambient space, yet it is evident that only those rays which pass through the pupil of the eye can affect the sense; and those rays also give the ideas of colour, according to the properties of those bodies which transmit or reflect them.

As the direction in which the extreme pencils of light cross each other in the eye, bears a due proportion to the angle in which they are transmitted from the object to the eye, it is evident that the image formed upon the retina will be proportioned to the apparent magnitude; and thus we have our first ideas of the size and distance of bodies, which, however, in many cases are corrected by experience. The nearer any object is to the eye, the larger is the angle by which it will appear in the eye, and therefore the greater will be the seeming magnitude of that body. In Plate II. fig. 24, let AB be an object viewed directly by the eye QR. From each extremity draw the lines AN and BM, intersecting each other in the crystalline humour at I. Then draw the line IK in the direction in which the eye is supposed to look at the object. The angle AIB is then the optical or visual angle; and the line IK is called the optical axis, because it is the axis of the lens or crystalline humour continued to the object.

The apparent magnitude of objects, then, depending thus on the angle under which they are seen, will evidently vary according to their distances. Thus different objects, as AB, CD, EF, the real magnitudes of which are very unequal, may be situated at such distances from the eye as to have their apparent magnitudes all equal; for if they are situated at such distances that the rays AN, BM, shall touch the extremities of each, they will then appear all under the same optical angle, and the diameter MN of each image on the retina will consequently be equal.

In the same manner objects of equal magnitude, situated at unequal distances, will appear unequal. For let AB and GH, two objects of equal size, be placed before the eye at different distances, IK and IS; draw the lines GP and HO, crossing each other in I; then OP, the image formed by the object GH on the retina, is evidently of a greater diameter than the image MN, which represents the object AB; in other words, the object GH will appear as large as an object of the diameter TV, situated at the same place as the object AB.

To render the subject still clearer, suppose the object HK (see Plate II. fig. 27) to be at a hundred yards distance, it will form an angle in the eye at A. At two hundred yards distance the angle it makes will be twice as small in the eye at B. Thus to whatever moderate distance the object is removed, the angle it forms in the eye will be proportionably less, and therefore the object will be diminished in the same proportion.

Hence it follows, that objects situated at different distances, whose apparent magnitudes are equal, are to each other as their distances from the eye; and by the same rule, equal objects situated directly before the eye, have their apparent magnitudes in a reciprocal proportion to their distances.

This last proposition must, however, be received with some allowance; for it is only applicable to very distant objects, and to those where the sense is not corrected by the judgment. For if the objects are near, we do not judge of their magnitude according to the visual angle. Thus, if a man of six feet high is seen at the distance of six feet under the very same angle as a dwarf of only two feet high at the distance of two feet, still the dwarf will not appear as large as the man, because the sense is corrected by the judgment.

In most cases, however, where the distance is considerable, the rule will be found accurate; and as it has its foundation in nature, most of the phenomena of vision will be explained by having recourse to the principles here laid down. If the eye is placed above a horizontal plain, the different parts of this plain will appear elevated in proportion to their distance, till at length they will appear upon a level with it. For in proportion as the different parts are more distant, the rays which proceed from them form angles with the optical axis IK (Plate II. fig. 24) more and more acute, and at length become almost parallel. This is the reason why, if we stand on the sea-shore, those parts of the ocean which are at a great distance appear elevated: for the globular form of the earth is not perceptible to the eye; and if it was, the apparent elevation of the sea is far greater than the arch which a segment of the globe would form within any distance that our eyes are capable of reaching.

For the same reason, if a number of objects are placed on the same plane and at the same height below the eye, the more distant will appear taller than the others; and if the same objects are placed on a similar plane above the eye, the more distant will appear the lowest.

The distant parts of a long wall, for the same reason, appear to a person who stands near one end to curve, or incline towards him. In the same manner the high wall of a lofty tower seems to a spectator, placed directly under it, to bend over him, and threaten him with instant destruction. If any person inclined to make the experiment will lie down on his back in a situation of this description, at the distance of five or six feet from the wall of which he contemplates the tremendous height, he will immediately be made sensible of the phenomenon.

If the distance between two objects forms an insensible angle, the objects, though in reality at some distance from each other, will appear contiguous. This is assigned by some astronomers as the reason why the ring or belt of Saturn appears as one mass of light, while they contend that it is formed from a number of little stars or satellites ranged within a certain distance of each other.

If the eye is carried along, as in a boat, without being sensible of its own motion, the objects which are stationary on each side will appear to move in a contrary direction. Thus we attribute to the sun and the other heavenly bodies a diurnal motion, which only affects the earth which we inhabit.

If two or three objects at a considerable distance, and on which the eye of the spectator is fixed, move with equal velocity past a third object which is at rest, the moving objects will appear to be actually at rest, and that which is really stationary will appear in motion. Thus the clouds which pass over the face of the moon appear at rest, while the moon itself appears to proceed rapidly along in an opposite direction. This happens, because the eye which is fixed upon the clouds follows their motion mechanically, and therefore the moon appears to move and not the clouds; as in the boat we do not perceive its motion, but conceive the banks are retiring behind us.

If the centre of the pupil, that is, the optic axis, is directed along the surface of any slender object in a perfectly right line, this line will appear only a point, because, in fact, the extremities only are visible.

An extended and distant arch, viewed by an eye which is exactly in the same line, will appear as a plane surface; because all the parts appearing equally distant, the curvature will not be perceived.

If a circle is viewed obliquely it will appear an oval, because the diameter which is perpendicular to the eye is shortened; in other words, the rays which proceed from the extremities form an angle so much the more acute as the obliquity is greater; on the contrary, the diameter which is parallel to the eye is apparently extended.

Such are the general principles upon which vision is performed; but the sense of sight is limited not only with respect to distant objects, but with respect to those which are near. Every person will easily perceive that if a book, or any other object, is held too close to the eye, the letters or the object will appear very indistinct and confused. This distance varies with respect to different eyes. Very near-sighted persons can see at the distance of one or two inches; but where the eye is in a sound state, the point of distinct vision varies from six to ten inches, or eight inches as a medium.

To understand the reason of this, it is necessary to remember that objects are made visible by cones of diverging rays proceeding from every luminous point of an object; but to have the object clearly painted on the retina, the rays must not enter the pupil of the eye too divergent. Indeed they ought to come in almost a parallel direction, more in the form of a cylinder than a cone, otherwise the humours of the eye will not make them converge at the proper points on the retina. Thus, let us suppose CD (Plate III. fig. 22) to be the diameter of the pupil of the eye; O is then a luminous point of any object situated at the distance of about six inches, and OC and OD are divergent rays proceeding from this point. Let AC and BD then be parallel rays. It will then be evident that the divergency of the rays OC and OD is so very small, that they are almost parallel when they arrive at the pupil; and consequently the eye will be able to converge them in such a degree as to produce distinct vision.

If, on the contrary, the point O was nearer to the pupil, or if the pupil was larger, they would fall more diverging upon the eye, and the image of the object would be formed at a point behind the retina, so as to be very imperfect and confused. Hence we may easily perceive the use of a single lens of a short focus, or high magnifying power, such as is employed in the single microscope. It renders these divergent rays less divergent; and consequently assists the eye in making them converge to that point which is necessary to distinct vision.

From the principles laid down it may easily be understood why very minute objects are imperceptible to the naked eye. If those objects could, consistently with distinct vision, be brought near to the eye, they would be perceived as well as by the aid of a microscope: hence some very near-sighted persons may be said to have microscopic eyes; but at six or eight inches (the limit of distinct vision) these objects subtend too small an angle to be perceptible. Opticians say that the eye is not capable of perceiving any object which subtends an angle of less than half a minute of a degree. The image on the retina is in this case less than the $\frac{1}{7200}$ part of an inch, and the object itself at six inches distance less than the $\frac{1}{1200}$ part of an inch broad. All smaller objects are invisible.

All very distant objects, upon the same principles, appear indistinct; for their images on the retina are so extremely small, that the distinction of parts is not perceptible. Thus if a man, of six feet stature, is viewed at the distance of a mile, his image on the retina will not be more than the thousandth part of an inch in length. We cannot be surprised, therefore, if the eye can discern nothing of his features, or the minuter parts of his body.

Distant objects, however, appear not only indistinct but obscure; and this last effect is from a deficiency of light, very many of the rays being intercepted in their passage through the air. Hence the difference in the appearance of such objects in a dark and cloudy day, when the air is impregnated with vapours, from that which they assume when the sun shines full and strong upon them.

With a single glass the defects in sight, with respect to many objects, either too near, or at too great a distance, for the persons labouring under them, are remedied; but there are cases where the object is so far distant, or so minute, that, though its outline may reach the eye, its parts must still, even with the aid of a single lens, be indistinctly perceived. The art of man has discovered a remedy, in a great degree, for this imperfection; and by means of a combination of glasses has opened a wide field for his researches into the wonders of nature: he can now trace the limbs of an insect invisible to the naked eye; or he can make the celestial objects appear to him as if their distance had been on a sudden diminished by many millions of miles.

Optical instruments.—From what has been stated concerning vision, the principle of the single microscope will be easily understood. Since the eye cannot have a distinct perception of any object at a nearer distance than six or eight inches, and since there are many objects which at that distance must be wholly imperceptible, or at best appear as points, an instrument which can render them visible, is a very desirable attainment.

It has been sufficiently explained that objects appear larger or smaller in proportion to the angle under which they are seen. Since therefore the rays by which small objects are rendered visible by the microscope, must come from the extreme points of that object, it is manifest that though the apparent magnitude is increased by the interposition of the lens, its real magnitude remains the same. The lens enables us to view it at a shorter distance; it will therefore appear exactly as much larger in diameter through the lens, as its distance from the glass is less than the nearest distance of distinct vision with the naked eye.

Let A (Plate III. fig. 1) be then a point of an object not visible to the eye at a less distance than AB, because the rays are too divergent for distinct vision. Now if the same object is placed in the focus C of the lens D, the rays which proceed from it will be rendered parallel by passing the lens; and therefore the object is rendered distinctly visible to the eye at E. It will then of course appear as much larger through the lens than to the naked eye, as CD is less than AB.

If the object AB is in the one focus of the lens DE, and the eye in the other focus F (fig. 2), as much of the object will be visible as is equal to the diameter of the lens; for the rays AD and BE proceed through the extremities of the lens, and are united at the focus F, and render the extreme parts of the object visible. Hence a maxim in optics, "that when an object is placed in one focus of a lens, and the eye in the other, the object appears just twice as large as it would to the naked eye, whatever the size of the lens:" for the lines FD and FE, if protracted to the distance of A and B, would form an image exactly twice as large. "If, on the other hand, the eye is nearer to the lens than the focus, it will see the object still larger; and if it is farther than the focus it will not see it so large; and in all cases the visible part of the object will be to the lens, as the focal distance of the lens is to the distance of the eye."

From what has been said, the reason will be very plain why the magnitude of objects seen through a double-convex lens, that is, a single microscope, will be in the proportion which the focus of the lens bears to the limits of distinct vision. Thus, suppose AB, fig. 1, to be that distance, or about six inches, so that the eye B can but just perceive the object A, and let the focal distance of the lens D be one-half of an inch; then since CD is but one-twelfth of AB, the length of the object at C will appear twelve times as large as at A, and its surface will appear magnified 144 times.

The most powerful single microscopes are very small globules of glass, which any curious person may make for himself by melting the ends of fine threads of glass in the flame of a candle; or by taking a little fine powdered glass on the point of a very small needle, and melting it into a globule in that way. It was with such microscopes as these that Lewenhoeck made all his wonderful discoveries, most of which are deposited in the British Museum.

The double or compound microscope differs from the preceding in this respect, that it consists of at least two lenses, by one of which an image is formed within the tube of the microscope; and this image is viewed through the eye-glass, instead of the object itself as in the single microscope. In this respect the principle is analogous to that of the telescope, only that, as the latter is intended to view distant objects, the object-lens is of a long focus, and consequently of a moderate magnifying power, and the eye-glass of a short focus, which magnifies considerably the image made by the object lens. Whereas the microscope being intended only for minute objects, the object-lens is consequently of a short focus, and the eye-glass in this case is not of so high a magnifying power.

A single figure will serve to explain the principles on which all these instruments are constructed. Suppose therefore LN (Plate III. fig. 3) to be the object-lens, and FG to be the eye-glass. The object OB is placed a little beyond the principal focus of LN. The cones or pencils of rays then proceeding from the different points of the object, are by the lens made to converge to their respective foci, and form an inverted image of the object at PQ. This image is seen through the eye-glass FG, and the rays of each pencil will proceed in a parallel direction to the pupil of the eye.

The compound microscope was thus originally constructed of two glasses, but it was found that what is called the field of view was too confined in instruments of this construction. For the pencil of rays which emanates from the point O of the object, and is converged by the lens to D, would proceed afterwards diverging towards H, and therefore would never arrive at the lens FG, nor enter the eye at E; but the pencils which proceed from *o* and *b* will be converged to the lens FG, and sent to the eye at E in a parallel direction. Hence if the object is large, a very small part of it will be visible, because several pencils will fall without the eye-glass FG, and the field of view will consequently be very limited.

To remedy this inconvenience, a broad lens DE is interposed, either of a plano-convex, or of a double-convex, form. By this, it will be perceived, the pencils which would have proceeded towards H and I, will be refracted to the eye-glass, and the figure will be completely formed as in the plate. This glass is called by opticians the body-glass, because it is situated in the body of the microscope. Some artists now make these instruments with two eye-glasses, made rather thin, which in some degree corrects what is called the aberration, or dispersion of the rays. In all these microscopes the object is seen in an inverted position; but this is of little importance with regard to small insects and other minute bodies.

The solar microscope is a kind of camera obscura, which, in a darkened chamber, throws the image on a wall or screen. It consists of two lenses fixed opposite a hole in a board or window-shutter; one, which condenses the light of the sun upon the object (which is placed between them), and the other which forms the image. There is also a plain reflector placed without, moved by a wheel and pinion, which may be so regulated as to throw the sun's rays upon the outer lens. The reader may form some idea of this by inspecting the Plate III. fig. 12, of the camera obscura, only supposing the figures on the wall to be a microscopic object magnified by the lens. Mr. Adams's most ingenious invention, the lucernal microscope, is also to be considered as a kind of camera obscura; only the light in this latter case proceeds from a lamp, instead of from the sun, which renders it convenient to be used at all times. But for a description of this elegant and most amusing instrument, we must refer to his Microscopical Essays.

From what has been said on the nature of the compound microscope, the principle of the telescope may be easily understood. Telescopes are, however, of two kinds: the one depending on the principle of refraction, and called the dioptric telescope; the other on the principle of reflection, and therefore termed the reflecting telescope.

The parts essential to a dioptric telescope are, the two lenses AD and EY (Plate III. fig. 4). As in the compound microscope, AD is the object-glass, and EY is the eye-glass; and these glasses are so combined in the tube, that the focus F of the one is exactly coincident with the focus of the other.

Let OB then represent a very distant object, from every point of which pencils of rays will proceed so little diverging to the object-lens AD, that they may be considered as nearly parallel; IM will then be the image which would be formed on a screen by the action of the lens AD. For supposing OA and BD two pencils of rays proceeding from the extreme points of the object, they will unite in the focal point F, and intersect each other. But the point F is also the focus of the eye-glass EY; and therefore the pencil of rays, instead of going on to diverge, will pass through it in nearly a parallel direction, so as to cause distinct vision.

It is then plain that, as in the compound microscope, it is the image which is here contemplated; and this will account for the common sensation when people say the object is brought nearer by a telescope. For the rays, which after crossing proceed in a divergent state, fall upon the lens EY, as if they proceeded from a real object situated at F. All that is effected by a telescope then is, to form such an image of a distant object, by means of the object-lens, and then to give the eye such assistance as is necessary for viewing that image as near as possible; so that the angle it shall subtend at the eye shall be very large compared with the angle which the object itself would subtend in the same situation. This is effected by means of the eye-glass, which refracts the pencils of rays, so that they may be brought to their several foci by the humours of the eye, as has been described.

To explain clearly, however, the reason why it appears magnified, we must again have recourse to the figure. OB being at a great distance, the length of the telescope is inconsiderable with respect to it. Supposing, therefore, the eye viewed it from the centre of the object-glass C, it would see it under the angle OCB: let OC and BC then be produced to the focus of the glass, they will then limit the image IM formed in the focus. If then two parallel rays are supposed to proceed to the eye-glass EY, they will be converged to its focus H, and the eye will see the image under the angle EHY. The apparent magnitude of the object seen by the naked eye is, therefore, to that of the image which is seen through the telescope, as the magnitude of the angle OCB, or ICM, to that of EHY, or IGM. Now the angle IGM is to ICM as CF to FG; that is, as the focal length of the object-glass to that of the eye-glass.

The magnifying power of these glasses may be augmented to a considerable degree, because the focal length of the object-glass, with respect to that of the eye-glass, may be greatly increased. This however would require a tube of immense length; because an eye-glass of a very short focus would cause such a dispersion of the rays of light, particularly towards the edges of the glass, that the view would be intercepted by the prismatic colours.

Another manifest defect in these telescopes is, that the image appears inverted: this, however, is of no consequence with respect to the heavenly bodies; and on this account it is still used as an astronomical telescope. One of almost a similar construction is also used on board of ships as a night-glass, to discover rocks in the ocean, or an enemy's fleet. Notwithstanding the inconvenience of exhibiting the objects inverted, more glasses than two cannot be employed from the paucity of light; and habit soon enables the persons who use them to discern objects with tolerable distinctness.

Galileo, who had heard of the invention of telescopes, but had not seen one, constructed a telescope upon theoretical principles, and adopted a concave lens as an eye-glass, but whether with a view of obviating the disagreeable effect produced by the inversion of the image or not is uncertain. This effect is however produced by the Galilean telescope, the construction of which is as follows: Let AB, fig. 5, be a very distant object, from every point of which pencils of rays proceed to the convex lens DE, and are refracted towards their foci at FSG. But a concave lens HI, the virtual focus of which is at FG, being interposed, the rays are not suffered to converge to that point; but being made less convergent, as is the effect of these glasses, enter the pupil almost parallel, and are converged by the humours of the eye to their proper foci on the retina at PQR: and the object will appear erect, because the pencils of rays cross each other only once, as in natural vision. Objects are seen very distinct through this telescope; but the field of view is so small, that its use is almost exclusively confined to the common opera-glasses. For if the focus of the eye-glass is short, the pencils of rays are rendered so divergent, that but a few of them can enter the pupil.

It was necessary then, to render the dioptric telescope useful for terrestrial purposes, to cause the image to be seen in an erect position. This was effected by the addition of two other convex lenses; of this Kepler suggested the idea, though it was not reduced to practice till thirty years after his time. The principle on which this telescope is constructed will be easily understood from what has been premised, and by inspecting the Plate, fig. 6. It will be seen there, that to the common astronomical telescope, there are added two other eye-glasses of the same focus as the first, LM and QR; and the first of these is placed at twice its focal distance from HI. After the rays therefore have passed the first eye-glass HI, instead of being received by the eye, as in the former case of the astronomical telescope, they pass on; the rays which constitute each pencil being rendered parallel: and in this state the respective pencils cross each other in the common focus, and the rays are received in this parallel state by the second eye-glass LM. The rays then constituting the respective pencils converge to their foci at NO, where a second image is formed, but inverted with respect to the former image EF. This then is the image which is viewed through the third eye-glass QR; and being in the same position as the object itself, is painted on the retina at XZY, and causes the object to be seen erect, as if no glasses had been interposed. The apparent magnitude of the object is not changed by these glasses; and depends, as before, on the focal lengths of the first object-glass and the lens nearest to it. The brilliancy of the object, however, will be diminished, since several rays will be lost in their passage through the two additional glasses. In placing the glasses in this telescope, care must be taken that the axes of the lenses coincide, or, as it is evident from our principles, indistinct vision only will be produced.

The brightness of the appearance through any of these telescopes or microscopes, depends chiefly on the aperture of the object-glass. For if the whole of that glass was covered except a small aperture in the middle, the magnitude of the image would not be altered; but fewer rays of every pencil being admitted, the object would appear obscure.

In few words, the apparent distinctness or confusion of any object, viewed through glasses, depends on the mutual inclination of the rays in any one pencil to each other, when they fall on the eye; the apparent magnitude depends upon the inclination of the rays of different pencils to each other; the apparent situation depends upon the real situation of the extreme pencils; and the apparent brightness or obscurity depends on the quantity of rays in each pencil.

As the magnifying power of all dioptric telescopes depends on the proportion which the focal length of the eye-glass bears to that of the object-glass; and as an eye-glass of very high magnifying powers could not be used on account of the aberration or dispersion of the rays, from the unequal thickness of the glass; various contrivances were invented for the sake of employing object-glasses of a very long focus. Wooden tubes of a very great length were found unmanageable. At length the famous Huygens invented a mode of dispensing with the tube. He attached the object-glass to a high pole, with a piece of mechanism which enabled him to raise or lower it at pleasure; and he made the eye-glass correspond to it by a silk cord, which he held tight in his hand. This method is, we believe, still in use on the continent for celestial objects, and distinguished by the name of the aerial telescope.

These inventions were however all rendered nugatory by the discovery of the reflecting telescope. For a dioptric or refracting telescope, even of one thousand feet focus, if it could be used, could not be made to magnify with distinctness above one thousand times; whereas a reflecting telescope of the length of eight or nine feet will magnify with distinctness 1200 times.

The well-known property in concave speculums, of causing the pencils of rays to converge to their foci, and there forming an image of any object that may be opposed to them, gave rise to the reflecting telescope. In this the effect is precisely the same as that produced by the dioptric telescope; only that in the one case it is produced by reflected, and in the other by refracted, light. Reflecting telescopes are made in various forms; and those principally in use in this country are distinguished by the names of their respective inventors, and are called the Newtonian, Gregorian, and Herschelian telescopes. The reflecting telescope on the Gregorian principle, which is the most common, as it is found to be the most convenient, is consructed in the following manner:

At the bottom of the great tube (Plate III. fig. 7) TTTT, is placed a large concave mirror DUVF, whose principal focus is at m: and in the middle of this mirror is a round hole P, opposite to which is placed the small mirror L, concave toward the great one; and so fixed to a strong wire M, that it may be removed further from the great mirror, or nearer to it, by means of a long screw in the inside of the tube, keeping its axis still in the same line Pmn with that of the great one. Now, since in viewing a very remote object, we oan scarcely see a point of it but what is, at least, as broad as the great mirror, we may consider the rays of each pencil, which flow from every point of the object, to be parallel to each other, and to cover the whole reflecting surface DUVF. But to avoid confusion in the figure, we shall only draw two rays of a pencil flowing from each extremity of the object into the great tube; and trace their progress through all their reflections and refractions to the eye f at the end of the small tube tt, which is joined to the great one.

Let us then suppose the object AB to be at such a distance, that the rays C may flow from its upper extremity A, and the rays E from its lower extremity B; then the rays C falling parallel upon the great mirror at D, will be thence reflected converging in the direction DG; and by crossing at I in the principal focus in the mirror, they will form the lower extremity of the inverted image IK, similar to the upper extremity A of the object AB; and passing on to the concave mirror L (whose focus is at n), they will fall upon it at g, and be thence reflected, converging in the direction gN, because gm is longer than gn; and passing through the hole P in the large mirror, they would meet somewhere about r, and form the upper extremity a of the erect image ab, similar to the upper extremity A of the object AB. But by passing through the plano-convex glass R in their way, they form that extremity of the image at a. In the same manner the rays E, which come from the bottom of the object AB, and fall parallel upon the great mirror at F, are thence reflected, converging to its focus; where they form the upper extremity I of the inverted image IK, similar to the lower extremity B of the object AB: and thence passing on to the small mirror L, and falling upon it at h, they are thence reflected in the converging state hO; and going on through the hole P of the great mirror, they would meet somewhere about q, and form there the lower extremity b of the erect image ab, similar to the lower extremity B of the object AB; but by passing through the convex glass R in their way, they meet and cross sooner, as at b, where that point of the erect image is formed. The like being understood of all those rays which flow from the intermediate points of the object between A and B, and enter the tube TT, all the intermediate points of the image between a and b will be formed; and the rays passing on from the image through the eye-glass S, and through a small hole e in the end of the lesser tube tt, they enter the eye f, which sees the image ab (by means of the eye-glass) under the large angle ced, and magnified in length under that angle from c to d.

In the best reflecting telescopes, the focus of the small mirror is never coincident with the focus m of the great one, where the first image IK is formed, but a little beyond it (with respect to the eye) as at n; the consequence of which is, that the rays of the pencils will not be parallel after reflection from the small mirror, but converge so as to meet in points about q, e, r; where they would form a larger upright image than ab, if the glass R was not in their way, and this image might be viewed by means of a single eye-glass properly placed between the image and the eye: but then the field of view would be less, and consequently not so pleasant; for that reason the glass R is still retained, to enlarge the scope or area of the field.

To find the magnifying power of this telescope, multiply the focal distance of the great mirror by the distance of the small mirror from the image next the eye, and multiply the focal distance of the small mirror by the focal distance of the eye-glass; then divide the product of the former multiplication by that of the latter, and the quotient will express the magnifying power. The difference between the Newtonian and Gregorian telescope is, that in the former the spectator looks in at the side through an aperture upon a plane mirror, by which the rays reflected from the concave mirror are reflected to the eye-glass; whereas in the latter the reader will see that he looks through the common eye-glass, which is in general more convenient.

The immensely powerful telescopes of Dr. Herschel are of a still different construction. This assiduous astronomer has made several specula, which are so perfect as to bear a magnifying power of more than six thousand times in diameter on a distant object. The object is reflected by a mirror as in the Gregorian telescope, and the rays are intercepted by a lens at a proper distance, so that the observer has his back to the object, and looks through the lens at the mirror. The magnifying power will in this case be the same as in the Newtonian telescope; but there not being a second reflector, the brightness of the object viewed in the Herschelian is greater than that in the Newtonian or Gregorian telescope. In conclusion, sir Isaac Newton's excellent maxim must not be omitted: "The art," says he, "of constructing good microscopes and telescopes may be said to depend on the circumstance of making the last image as large and distinct and luminous as possible."

There are some instruments of rather an amusing than a useful description, the effects of which depend on a proper combination of plane or convex glasses. Our limits will not admit the notice of more than two of this kind, namely, the magic lanthorn, and the camera obscura. The former is a microscope upon the same principles as the solar microscope, and may be used with good effect for magnifying small transparent objects; but in general it is applied to the purpose of amusement, by casting the image of a small transparent painting on glass upon a white wall or screen, at a proper distance from the instrument.

Let a candle or lamp C (fig. 8) be placed in the inside of a box, so that the light may pass through the plano-convex lens NN, and strongly illuminate the object OB; which is a transparent painting on glass, inverted and moveable before NN, by means of a sliding piece in which the glass is set or fixed. This illumination is still more increased by the reflection of light from a concave mirror SS, placed at the other end of the box, which causes the light to fall upon the lens NN, as represented in the figure. Lastly, a lens LL, fixed in a sliding tube, is brought to the requisite distance from the object OB, and a large erect image IM is formed upon the opposite wall.

The camera obscura has the same relation to the telescope as the solar microscope has to the common double microscope, and is thus constructed:

Let CD (fig. 12) represent a darkened chamber perforated at L, where a convex lens is fixed, the curvature of which is such, that the focus of parallel rays falls upon the opposite wall. Then if AB is an object at such a distance that the rays which proceed from any given point of its surface to the lens L may be esteemed parallel, an inverted picture will be formed on the opposite wall; for the pencil which proceeds from A will converge to *a*, and the pencil which proceeds from B will converge to *b*, and the intermediate points of the object will be depicted between *a* and *b*.

For the use of painters these instruments are now constructed in a very convenient mode. The lens is made to slide in a small wooden box, so as to be easily adjusted to a proper focus; and the image falls upon a plane mirror, placed obliquely at the back part of the box, from which it is reflected on a piece of ground glass, or on a sheet of white paper extended over. The picture which is thus formed is very tender and beautiful. The moving objects give it animation; and the outline formed is so perfect that it may be easily traced, even by a person who is little skilled in drawing or perspective.

Of the doctrine of colours, or chromatics.—In some of the preceding sections we had occasion to use the word aberration, though we had not then an opportunity of explaining it; since in the optics of the mind, as well as in those of which we are treating, when too many images are presented at once, a certain degree of confusion must necessarily ensue. As there is no "royal road to science," so philosophy gradually developes her secrets, and the possession of one fact prepares the mind for another.

We have hitherto assumed as a principle, that a convex lens unites in one point, which we have called the focus, all the rays proceeding from any given point of an object. If this was exactly the case, the images formed by these glasses would be perfectly distinct and unconfused. The principle, however, holds strictly true only with respect to those rays which pass nearly through the centre of the lens; for those which pass near the extremities or edges of the glass, meet in foci still more distant, and from this multiplication of images great indistinctness results.

To shew the reason of this it is necessary to have recourse to a figure. Let PP then (Plate III. fig. 10) be a convex lens; and *Ee* an object, the point E of which corresponds with the axis of the lens, and sends forth the rays EM, EN, EA, EM, and EN, all of which reach the surface of the glass, but in different parts. Now it is manifest, upon the principles already explained, that the ray EA, which passes through the middle of the glass, suffers no refraction; the rays EM, EM, also, which pass through near to EA, will be converged to a focus at F, which we have been accustomed to consider as the focus of the lens. But the rays EN, EN, which are nearer to the edge of the glass, will be differently refracted; and will meet about G, nearer to the lens, where they will form another image G*g*. Hence it is evident that the first image F*f* is formed only by the union of those rays which pass very near the centre of the lens; but, in truth, as the rays of light proceeding from every point of an object are very numerous, there is a succession of images formed according to the parts of the lens where they penetrate, which necessarily produces great indistinctness and confusion; and this is what is meant by the word aberration.

This confusion or dispersion of the rays is increased in proportion as the arcs PAP, PBP, are larger segments of their respective circles: hence in very thick and convex lenses the aberration is such as to be intolerable. Even in the object-glasses of telescopes, though they are made thin, and are segments of large circles, and though from these reasons the dispersion of the rays may be insensible in itself, still the magnifying power multiplies it as often as the object itself. Hence the greater the magnifying power, the smaller should be the aperture of the object-glass; and when the dispersion of the rays is very great, the defect is in some degree remedied by covering the edge of the lens with an opaque ring; but in this case, while distinctness is restored, the brightness of the image is necessarily diminished. Opticians have therefore endeavoured to form such combinations of lenses, both concave and convex, varying in their respective foci, as must unite all the rays in a single point, and thus present a distinct image. Calculations have been formed for these combinations, but the hand of the artist has never been able to bring the speculations of theorists to entire perfection.

The plan most generally adopted by practical opticians is, to combine two shallow lenses together in such a manner that they act as a single lens. They use often plano-convex, for that figure admits of less aberration than any other; but shallow lenses of a double-convex kind will answer. In this combination the lenses are set near together, so that the second lens acts only in bringing the rays which pass through the first to a nearer focus. Thus in Plate III. fig. 9, AB and CD are two lenses of this description; and the focus of AB would be at F, but, by the second lens, the rays are made to converge at a nearer focus *f*: thus they act together as a single lens of double their magnifying power, with this advantage; that as the curvatures of both conjointly, are less than the curvature of a single lens of equal power, the aberration is greatly lessened.

The aberration which we have been describing results from the spherical form of the glasses; but there is another kind of aberration, which depends immediately upon the nature and properties of light itself. Each ray or beam of light, indeed, which gives us the sensation of white, is found to be compounded of seven other rays; and these component rays are each of them differently refrangible. Hence objects viewed through very convex glasses are often found to have their edges tinged with various colours. This effect was long felt, but it remained for Newton to explain the cause.

In the short history contained in the first part of this article, the discoveries on colours were briefly related; but it will perhaps be satisfactory to the reader to have the experiment described in the words of Newton himself, which will at the same time afford an example of the style and manner of this first of philosophers.

"In a very dark chamber, at a round hole F (Plate III. fig. 14), about one-third of an inch broad (says he), made in the shutter of a window, I placed a glass prism ABC, whereby the beam of the sun's light, SF, which came in at that hole, might be refracted upwards, toward the opposite wall of the chamber, and there form a coloured image of the sun, represented at PT. The axis of the prism (that is, the line passing through the middle of the prism, from one end of it to the other end, parallel to the edge of the refracting angle) was in this and the following experiments perpendicular to the incident rays. About this axis I turned the prism slowly; and saw the refracted light on the wall, or coloured image of the sun, first to descend, and then to ascend. Between the descent and ascent, when the image seemed stationary, I stopped the prism, and fixed it in that posture.

"Then I let the refracted light fall perpendicularly upon a sheet of white paper, MN, placed at the opposite wall of the chamber; and observed the figure and dimensions of the solar image PT, formed on the paper by that light. This image was oblong, and not oval, but terminated by two rectilinear and parallel sides, and two semicircular ends. On its sides it was bounded pretty distinctly; but on its ends very confusedly and indistinctly, the light there decaying and vanishing by degrees. At the distance of $18\frac{1}{2}$ feet from the prism, the breadth of the image was about $2\frac{5}{8}$ inches, but its length was about $10\frac{1}{4}$ inches, and the length of its rectilinear sides about 8 inches; and ACB, the refracting angle of the prism, whereby so great a length was made, was 64°. With a less angle the length of the image was less, the breadth remaining the same. It is farther to be observed, that the rays went on in straight lines from the prism to the image; and therefore at their going out of the prism had all that inclination to one another from which the length of the image proceeded. This image PT was coloured, and the more eminent colours lay in this order from the bottom at T to the top at P; red, orange, yellow, green, blue, indigo, violet, together with all their intermediate degrees, in a continual succession, perpetually varying."

The philosopher continued his experiments, and by making the rays thus decompounded pass, as was formerly related, through a second prism, he found that they did not admit of farther decomposition; and that objects placed in the rays producing one colour always appeared to be of that colour. He then examined the ratio between the sines of incidence and refraction of these decompounded rays; and found that each of the seven primary colour-making rays, as they may be called, had certain limits within which they were confined. Thus, let the sine of incidence in glass be divided into fifty equal parts, the sine of refraction into air of the least and most refrangible rays will contain respectively 77 and 78 such parts. The sines of refraction of all the degrees of red will have the intermediate degrees of magnitude, from 77 to $77\frac{1}{8}$; orange from $77\frac{1}{8}$ to $77\frac{1}{5}$; yellow from $77\frac{1}{5}$ to $77\frac{1}{3}$; green from $77\frac{1}{3}$ to $77\frac{1}{2}$; blue from $77\frac{1}{2}$ to $77\frac{2}{3}$; indigo from $77\frac{2}{3}$ to $77\frac{7}{9}$; and violet from $77\frac{7}{9}$ to 78.

According to the properties of bodies in reflecting or absorbing these rays, the colours which we see in them are formed. If every ray falling upon an object was reflected to our eyes it would appear white; if every ray was absorbed it would appear black; between these two appearances innumerable species of colours may be formed by reflection or transmission of the various combinations of the colour-making rays. If the rays also of light were not thus compounded, every object would appear of the same colour, and an irksome uniformity would prevail over the face of nature.

To leave, however, for the present, the further prosecution of this subject, and to return to that of the errors arising in optical glasses from the dispersion of the rays of light, it must be evident that, in proportion as any part of a glass bears a resemblance to the form of a prism, the component rays must be necessarily separated. The edges of every convex lens approach to this form; and it is on this account that the extremities of objects viewed through them are found to be tinged with coloured rays. In reality, as all the different colour-making rays are differently refrangible, in such a glass these different rays will have different foci, and will form their respective images at different distances from the glass. Thus imagine PP (Plate III. fig. 11) to be a double-convex lens, and OO an object situated at some distance from it. If the object OO was red, the rays proceeding from it would form a red image at R*r*; if it was violet, an image of that colour would be formed at V*v* nearer the glass; and if the object was white, or any other combination of the colour-making rays, these rays would have their respective foci at different distances from the glass, and form a succession of images, in the order of the prismatic colours, between the space R*r* and V*v*.

This dispersion depends on the focal length of the glass, the space which the coloured images occupy being about the 28th part. Thus, if the glass is of 28 feet focus, the space between R*r* and V*v* will be about one foot, and so in proportion. Now when viewed through one eye-glass or more, this succession of images will seem to form but one image, but that very indistinct, and tinged with various colours; and as the red image R*r* in the figure is largest, or seen under the greatest angle, the extreme parts of this confused image will be red, and a succession of the prismatic colours will be formed with this red fringe, as is frequently found in telescopes upon the old construction.

This defect in telescopes was long regarded as without a remedy; but who shall set bounds to the inventive powers of the human mind? It was in the different refractive powers of various media that a remedy was sought for this property in glasses, so adverse to the hopes and wishes of philosophers. Sir Isaac Newton had hinted the practicability of this plan; but he was too deeply engaged in the vast discoveries which the use of the reflector opened to his view, to pursue practically the idea. As water is known to have very different refractive powers from glass, the great Euler, proceeding upon the hint of Newton, projected an object-glass of two lenses, with water between them. The memoir of Euler excited powerfully the attention of Mr. Dollond, a practical optician in London; and after trying the refractive power of water combined with glass in the form of a prism, he conceived that the refractive powers of different glasses might serve to correct each other. He applied himself therefore to examine the qualities of every kind of glass he could procure, and found that the two which differed most essentially in their refractive powers were the common crown or window glass, and the white flint glass. He then formed two prisms, one of the white flint of an angle of about 25 degrees, and another of flint of 29. They refracted very nearly alike, but their power of making the colours diverge was very different. He next ground several others of crown glass, till he procured one which was equal as to the divergency of light with that of the flint glass. He placed them together, therefore, but in opposite directions, so as to counteract each other; and he found that the light which passed through them was perfectly white. This discovery, it was obvious, was immediately applicable to the object-glasses of telescopes. To make the glasses act as the two prisms, to refract the light in contrary directions, it was plain that the one must be concave and the other convex; and as the rays are to converge to a real focus, the excess of refraction must be in the convex lens. As the convex lens is to refract most also, it appeared from his experiments that it must be of crown glass. He therefore employed two convex lenses of crown glass, with a concave lens of flint glass; and these are the telescopes most in use at present, and well known by the name of achromatic telescopes. Some opticians however, we believe, now construct them with two lenses, one convex and the other concave.

In fig. 13, *a* and *c* shew the two convex lenses, and *bb* the concave one, of this telescope. They are all ground to spheres of different radii, according to the refractive powers of the different kinds of glass, and the intended focal distance of the object-glass of the telescope. According to Boscovich, the focal distance of the parallel rays for the concave lens is one-half, and for the convex glass one-third, of the combined focus. When put together they refract the rays in the following manner: Let *ab*, *ab* (fig. 18), be two red rays of the sun's light falling parallel on the first convex lens *c*. Supposing there was no other lens present but that one, they would then be converged into the lines *be*, *be*, and at last meet in the focus *q*. Let the lines *gh*, *gh*, represent two violet rays falling on the surface of the lens. These are also refracted, and will meet in a focus; but as they have a greater degree of refrangibility than the red rays, they must of consequence converge more by the same power of refraction in the glass, and meet sooner in a focus, suppose at *r*. Let now the concave lens of flint glass *dd* be placed in such a manner as to intercept all the rays before they come to their focus. If this lens was made of the same materials, and ground to to the same radius with the convex one, it would have the same power to cause the rays to diverge that the former had to make them converge. In this case, the red rays would become parallel, and move on in the line *oo*, *oo*: but the concave lens, being made of flint glass, and upon a shorter radius, has a greater refractive power, and therefore they diverge a little after they come out of it; and if no third lens was interposed, they would proceed diverging in the lines *opt*, *opt*; but, by the interposition of the third lens *ovo*, they are again made to converge, and meet in a focus somewhat more distant than the former, as at *x*. By the concave lens the violet rays are also refracted, and made to diverge: but, having a greater degree of refrangibility, the same power of refraction makes them diverge somewhat more than the red ones; and thus, if no third lens was interposed, they would proceed in such lines as *lmn*, *lmn*. As the differently-coloured rays then fall upon the third lens with different degrees of divergence, it is plain that the same power of refraction in that lens will operate upon them in such a manner as to bring them all together to a focus very nearly at the same point. The red rays, it is true, require the greatest power of refraction to bring them to a focus; but they fall upon the lens with the least degree of divergence. The violet rays, though they require the least power of refraction, yet have the greatest degree of divergence; and thus all meet together at the point *x*, or very nearly so. It was afterwards demonstrated by M. Zeiker of Petersburgh, that it is the lead used in the composition of the crown glass, which gives it this remarkable property of dispersing the extreme rays; and he found that this property was increased in proportion to the quantity of minium, or red lead, which was employed in the manufacture of the glass.

The more we investigate the works of nature, the greater reason have we to admire the wisdom of its author, and that wonderful adaptation of our organs, in the minuter particulars, to the general laws which pervade the universe. The subject before us affords a striking instance to corroborate this remark. We have hitherto supposed the eye to be a lens capable only of enlarging and contracting, and consequently, from the description now given of the rays of light, it must be incapable of obviating the confusion which must arise from their different degrees of refrangibility. But here the use of that wonderful structure of parts, and the different fluids in the eye, is clearly seen. The eye is, in fact, a compound lens. Each fluid has its proper degree of refrangible power. The shape of the lenses is altered at will, according to the distance of the object; and the three substances having the proper powers of refrangibility, the effects of an achromatic glass are without difficulty produced by the eye, whose mechanical structure and exact arrangement of substances it is in vain for the art of man to imitate.

From what has been stated, the principal phenomena of colours may, without much difficulty, be explained.

If all the different-coloured rays which the prism affords are reunited in the focus of a convex lens, the produce will be white; yet these same rays, which, taken together, form white, give, after the point of their reunion, that is, beyond the point where they cross each other, the same colours as those which departed from the prism, but in a reversed order, by the crossing of the rays: the reason of which is clear; for the ray being white before it was divided by the prism, must necessarily become so by the reunion of its parts, which the difference of refrangibility had separated, and this reunion cannot in any manner tend to alter or destroy the nature of the colours; it follows then that they must appear again beyond the point of crossing. A similar effect will be produced, if the dispersed rays are received from the prism upon a concave reflector. In the focus of the reflector they will unite and form a white or colourless image of the sun. But it is curious to remark, that if any one of the colours is stopped in its progress to the reflector by the interposition of a wire, or any other slender opaque body, then the image in the focus will be an imperfect white, or a mixed colour. Beyond the focus the rays separate again, as in the case of their passing through a convex lens, and form the coloured spectrum, only the order of the colours from the crossing of the rays is inverted.

In the same manner, if we mix a certain proportion of red colour with orange, yellow, green, blue, indigo, and violet, a colour will be produced which resembles that which is made by mixing a little black with white, and which would be entirely white if some of the rays were not lost or absorbed by the grossness of the colouring matter.

A colour nearly approaching to white, is also formed by colouring a piece of round pasteboard with the different prismatic colours, and causing it to be turned round so rapidly, that no particular colour can be perceived.

If to a single ray of the sun, divided by the prism, which will then form an oblong coloured spectrum, a thick glass deeply coloured with one of the primitive colours is applied, for example red, the light which passes through will appear red only, and will form a round image.

The component rays of light may be separated by other means than by the prism. It is a common amusement of children to blow round bubbles of soap, dissolved in water, from the bowl of a tobacco-pipe; and these bubbles will, in the sunshine, commonly exhibit most of the prismatic colours. Indeed the same thing may be at any time observed in the bubbles made by agitating soap and water. As these bubbles are thin vesicles of the matter dissolved in the fluid, they are commonly supposed to vary in their thickness, and to act in this way in separating the rays. If two pieces of glass, also of an unequal surface, are gently pressed together, round the point of contact circles of different colours will be formed. Sir Isaac Newton employed for this experiment the object-glasses of two telescopes of a long focus, which it is well known are much less convex than the common spectacle-glasses. One was a plano-convex for a telescope of 14 feet, and the other a double-convex for one of 50 feet. Upon pressing the glasses close together, at the point of contact circles of coloured light appeared, and they increased in number and size as the pressure was increased. The order of the colours next to the point in contact, which was black, was blue, yellow, white, yellow, and red. Without this circle another appeared, consisting of violet, blue, green, yellow, and red. A third succeeded of purple, blue, green, yellow, and red; and a fourth of green and red. The outer circles were paler, and more obscure, than those within.

The appearance of these circles is delineated in fig. 15. where *a*, *b*, *c*, *d*, *e*; *f*, *g*, *h*, *i*, *k*; *l*, *m*, *n*, *o*, *p*; *q*, *r*; *s*, *t*; *u*, *x*; *y*, *z*; denote the colours in order from the centre, namely, black, blue, green, yellow, red; purple, blue, green, yellow, red; green, red: greenish blue, red; greenish blue; reddish white.

Various theories have been offered to account for this separation of the rays, but none of them are quite satisfactory. Perhaps if Mr. Deleval's experiments on transmitted and reflected light were carefully pursued, they might afford some illustration of the phenomenon.

If two thick glasses, the one red and the other green, are placed one upon another, they will produce a perfect opacity, though each of them, taken separately, is transparent; because the one permits the red rays only to pass through it, and the other only green ones; therefore when these two glasses are united, neither of those kind of rays can reach the eye; because the first permits only red rays to pass, and green ones are the only rays which the second can transmit.

If the rays of the sun are made to fall very obliquely upon the interior surface of a prism, the violet-coloured rays will be reflected, and the red, &c. will be transmitted; if the obliquity of incidence is augmented the blue will be also reflected, and the other transmitted; the reason of which is, that the rays which have the most refrangibility are also those which are the easiest reflected.

In whatever manner we examine the colour of a single prismatic ray, we shall always find, that neither refraction, reflection, nor any other means, can make it forego its natural hue; but if we examine the artificial colouring of bodies by a microscope, it will appear a rude heap of colours, unequally mixed. If we mix a blue and yellow to make a common green, it will appear moderately beautiful to the naked eye; but when we regard it with microscopic attention, it seems a confused mass of yellow and blue parts, each particle reflecting but one separate colour.

Of the rainbow, and other remarkable phenomena of light.—Since the rays of light are found to be decompounded by refracting surfaces, we can no longer be surprised at the changes produced in any object by the intervention of another. The vivid colours which gild the rising or the setting sun, must necessarily differ from those which adorn its noon-day splendour. There must be the greatest variety which the liveliest fancy can imagine. The clouds will assume the most fantastic forms, or will lour with the darkest hues, according to the different rays which are reflected to our eyes, or the quantity absorbed by the vapours in the air. The ignorant multitude will necessarily be alarmed by the sights in the heavens; by the appearance at one time of three, at another of five, suns; of circles of various magnitudes round the sun or moon; and thence conceive that some fatal change must take place in the physical or the moral world, some fall of empires or tremendous earthquake: while the optician contemplates them merely as the natural and beautiful effects produced by clouds or vapour in various masses upon the rays of light.

One of the most beautiful and common of these appearances deserves particular investigation, as, when this subject is well understood, there will be little difficulty in accounting for others of a similar nature, dependant on the different refrangibility of the rays of light. Frequently, when our backs are turned to the sun, and there is a shower either around us, or at some distance before us, a bow is seen in the air, adorned with all or some of the seven primary colours. The appearance of this bow, in poetical language called the iris, and in common language the rainbow, was an inexplicable mystery to the antients; and, though now well understood, continues to be the subject of admiration to the peasant and the philosopher.

We are indebted to sir Isaac Newton for the explanation of this appearance; and by various easy experiments we may convince any man that his theory is founded on truth. If a glass globe is suspended in the strong light of the sun, it will be found to reflect the different prismatic colours exactly in proportion to the position in which it is placed; in other words, agreeably to the angle which it forms with the spectator's eye and the incidence of the rays of light. The fact is, that innumerable pencils of light fall upon the surface of the globe, and each of these is separated as by a prism. To make this matter still clearer, let us suppose the circle BAW (Plate III. fig. 16) to represent the globe, or a drop of rain, for each drop may be considered as a small globe of water. The red rays, it is well known, are least refrangible; they will therefore be refracted, agreeably to their angle of incidence, to a certain point A in the most distant part of the globe; the yellow, the green, the blue, and the purple rays, will each be refracted to another point. A part of the light, as refracted, will be transmitted, but a part will also be reflected; the red rays at the point A, and the others at certain other points, agreeably to their angle of refraction.

It is very evident that if the spectator's eye is placed in the direction of MW, or the course of the red-making rays, he will only distinguish the red colour; if in another situation, he will see only by the yellow rays; in another by the blue, &c.: but as in a shower of rain there are drops at all heights and all distances, all those that are in a certain position with respect to the spectator will reflect the red rays, all those in the next station the orange, those in the next the green, &c.

To avoid confusion let us, for the present, imagine only three drops of rain, and three degrees of colours in the section of a bow (Plate III. fig. 20). It is evident that the angle CEP is less than the angle BEP, and that the angle AEP is the greatest of the three. This largest angle then is formed by the red rays, the middle one consists of the green, and the smallest is the purple. All the drops of rain, therefore, that happen to be in a certain position to the eye of the spectator, will reflect the red rays, and form a band or semicircle of red; those again in a certain position will present a band of green, &c. If he alters his station, the spectator will still see a bow, though not the same bow as before; and if there are many spectators they will each see a different bow, though it appears to be the same.

There are sometimes seen two bows, one formed as has been described, the other appearing externally to embrace the primary bow, and which is sometimes called a secondary or false bow, because it is fainter than the other; and what is most remarkable is, that in the false bow the order of the colours appears always reversed.

In the true or primary bow we have seen that the rays of light arrive at the spectator's eye after two refractions and one reflection; in the secondary bow the rays are sent to our eyes after two refractions and two reflections, and the order of the colours is reversed, because in this latter case the light enters at the inferior part of the drop, and is transmitted through the superior. Thus (fig. 19) the ray of light which enters at B is refracted to A, whence it is reflected to P, and again reflected to W, where, suffering another refraction, it is sent to the eye of the spectator. The colours of this outer bow are fainter than those of the other, because, the drop being transparent, a part of the light is transmitted, and consequently lost, at each reflection.

The phenomenon assumes a semicircular appearance, because it is only at certain angles that the refracted rays are visible to our eyes. The least refrangible, or red rays, make an angle of 42 degrees two minutes, and the most refrangible or violet rays an angle of 40 degrees 17 minutes. Now if a line is drawn horizontally from the spectator's eye, it is evident that angles formed with this line, of a certain dimension in every direction, will produce a circle; as will be evident by only attaching a cord of a given length to a certain point, round which it may turn as round its axis, and in every point will describe an angle with the horizontal line of a certain and determinate extent.

Let HO, for instance (Plate III. fig. 19), represent the horizon, BW a drop of rain at any altitude, SB a line drawn from the sun to the drop, which will be parallel to a line SM drawn from the eye of the spectator to the sun. The course of part of the decompounded ray SB may be first by refraction from B to A, then by reflection from A to W, lastly by refraction from W to M. Now all drops, which are in such a situation that the incident and emergent rays SB, MW, produced through them make the same angle SNM, will be the means of exciting in the spectators the same idea of colour. Let MW turn upon HO as an axis, till W meets the horizon on both sides, and the point W will describe the arc of a circle: and all the drops placed in its circumference will have the property we have mentioned, of transmitting to the eye a particular colour. When the plane HMWA is perpendicular to the horizon, the line MW is directed to the vertex of the bow, and WK is its altitude.

This altitude depends on two things, the angle between the incident and emergent rays, and the height of the sun above the horizon; for since SM is parallel to SN, the angle SNM is equal to NMI: but SMH, the altitude of the sun, is equal to KMI; therefore the altitude of the bow WMK, which is equal to the difference between WMI and KMI, is equal to the difference between the angles made by the incident and emergent rays and the altitude of the sun.

The angle between the incident and emergent rays is different for the different colours, as was already intimated; for the red, or least refrangible, rays, it is equal to 42° 2′; for the violet, or most refrangible, it is equal to 40 17′; consequently when the sun is more than 42° 2′ above the horizon, the red colour cannot be seen; when it is above 40° 17′ the violet colour cannot be seen.

The secondary bow is made in a similar manner; but the sun's rays suffer, in this case, two reflections within the drop. The ray SB (Plate III. fig. 19) is decompounded at B; and one part is refracted to A, thence reflected to P, and from P reflected to W, where it is refracted to M. The angle between the incident and emergent rays SNM is equal as before to NMI; and NMK, the height of the bow, is equal to the difference between the angle made by the incident and emergent rays and the height of the sun. In this case the angle SNM, for the red rays, is equal to 50° 7′, and for the violet rays it is equal to 54° 7′; consequently the upper part of the secondary bow will not be seen when the sun is above 54° 7′ above the horizon, and the lower part of the bow will not be seen when the sun is 50° 7′ above the horizon.

In the same manner innumerable bows might be formed by a greater number of reflections within the drops; but as the secondary is so much fainter than the primary, that all the colours in it are seldom seen, for the same reason a bow made with three reflections would be fainter still, and in general altogether imperceptible. Since the rays of light, by various reflections and refractions, are thus capable of forming, by means of drops of rain, the bows which we so frequently see in the heavens, it is evident that there will be not only solar and lunar bows, but that many striking appearances will be produced by drops upon the ground, or air on the agitated surface of the water. Thus a lunar bow will be formed by rays from the moon affected by drops of rain; but as its light is very faint in comparison with that of the sun, such a bow will very seldom be seen, and the colours of it, when seen, will be faint and dim.

The marine or sea bow is a phenomenon sometimes observed in a much agitated sea; when the wind, sweeping part of the tops of the waves, carries them aloft, so that the sun's rays, falling upon them, are refracted, &c. as in a common shower, and paint the colours of the bow.

Rohault mentions coloured bows on the grass, formed by the refraction of the sun's rays in the morning dew.

Dr. Langwith, indeed, once saw a bow lying on the ground, the colours of which were almost as lively as those of the common rainbow. It was extended several hundred yards. It was not round, but oblong, being, as he conceived, the portion of an hyperbola. The colours took up less space, and were much more lively, in those parts of the bow which were near him than in those which were at a distance.

The drops of rain descend in a globular form, and thence we can easily account for the effects produced by them on the rays of light; but in different states of the air, instead of drops of rain, vapour falls to the earth in different forms of sleet, snow, and hail. In the two latter states there cannot be a refraction of the rays of light; but in the former state, when a drop is partly in a congealed and partly in a fluid form, the rays of light will be differently affected, both from the form of the drop and its various refracting powers. Hence we may expect a variety of curious appearances in the heavens; and to these drops, in different states, we may attribute the formation of halos, parhelia, and many other phenomena, detailed in the Philosophical Transactions, or in the histories of every country.

The halo, or corona, is a luminous circle surrounding the sun, the moon, a planet, or a fixed star. It is sometimes quite white, and sometimes coloured like the rainbow. Those which have been observed round the moon or stars are but of a very small diameter; those round the sun are of different magnitudes, and sometimes immensely great. When coloured, the colours are fainter than those of the rainbow, and appear in a different order, according to their size. In those which sir Isaac Newton observed in 1692, the order of the colours, from the inside next the sun, was in the innermost blue, white, red; in the middle purple, blue, green, yellow, pale red; in the outermost pale blue, and pale red. Huygens observed one red next the sun, and pale blue at the extremity. Mr. Weidler has given an account of one yellow on the inside, and white on the outside. In France one was observed, in which the order of the colours was white, red, blue, green, and a bright red on the outside.

Artificial coronas may be made in cold weather, by placing a lighted candle in the midst of a cloud of steam; or if a glass window is breathed upon, and the flame of a candle placed at some distance from the window, while the operator is also at the distance of some feet from another part of the window, the flame will be surrounded with a coloured halo.

When M. Bouguer was on the top of mount Pichinea, in the Cordilleras, he and some gentlemen who accompanied him, observed a most remarkable phenomenon. When the sun was just rising behind them, and a white cloud was about thirty paces from them, each of them observed his own shadow (and no other) projected upon it. All the parts of the shadow were distinct; and the head was adorned with a kind of glory, consisting of three or four concentric crowns, of a very lively colour, each exhibiting all the varieties of the primary rainbow, and having the circle red on the outside.

Similar to this appearance was one which occurred to Dr. M'Fait, in Scotland. This gentleman observed a rainbow round his shadow in a mist, when he was situated on an eminence above it. In this situation the whole country appeared to be immersed in a vast deluge, and nothing but the tops of hills appeared here and there above the flood; at another time he observed a double range of colours round his shadow.

The parhelia, or mock suns, are the most splendid appearances of this kind. We find these appearances frequently adverted to by the antients, who generally considered them as formidable omens. Four mock suns were seen at once by Scheiner at Rome, and by Muschenbroeck at Utrecht; and seven were observed by Hevelius at Sedan, in 1661.

The parhelia generally appear about the size of the true sun, not quite so bright, though they are said sometimes to rival their parent luminary in splendour. When there are a number of them they are not equal to each other in brightness. Externally they are tinged with colours like the rainbow. They are not always round, and have sometimes a long fiery tail opposite the sun, but paler towards the extremity. Dr. Haller observed one with tails extending both ways. Mr. Weidler saw a parhelion with one tail pointing up and another downward, a little crooked; the limb which was farthest from the sun being of a purple colour, the other tinged with the colours of the rainbow.

Coronas generally accompany parhelia: some coloured, and others white. There is also, in general, a very large white circle, parallel to the horizon, which passes through all the parhelia; and, if it was entire, would go through the centre of the sun: sometimes there are arches of smaller circles concentric to this, and touching the coloured circles which surround the sun; they are also tinged with colours, and contain other parhelia.

One of the most remarkable appearances of this kind was that which was observed at Rome by Scheiner, as intimated above; and this may serve as a sufficient instance of the parhelion.

This celebrated phenomenon is represented in Plate III. fig. 17, in which A is the place of the observer, B his zenith, C the true sun, and AB a plane passing through the observer's eye, the true sun, and the zenith. About the sun C there appeared two concentric rings, not complete, but diversified with colours. The lesser of them, DEF, was fuller, and more perfect; and though it was open from D to F, yet those ends were perpetually endeavouring to unite, and sometimes they did so. The outer of these rings was much fainter, so as scarcely to be discernible. It had, however, a variety of colours, but was very inconstant. The third circle, KLMN, was very large, and entirely white, passing through the middle of the sun, and every where parallel to the horizon. At first this circle was entire; but towards the end of the phenomenon it was weak and ragged, so as hardly to be perceived from M towards N.

In the intersection of this circle and the outward iris GKI, there broke out two parhelia, or mock suns, N and K, not quite perfect, K being rather weak, but N shone brighter and stronger. The brightness of the middle of them was something like that of the sun; but towards the edges they were tinged with colours like those of the rainbow, and they were uneven and ragged. The parhelion N was a little wavering; and sent out a spiked tail NP, of a colour somewhat fiery, the length of which was continually changing.

The parhelia at L and M, in the horizontal ring, were not so bright as the former, but were rounder, and white, like the circle in which they were placed. The parhelion N disappeared before K; and while M grew fainter, K grew brighter, and vanished the last of all.

It is to be observed farther, that the order of the colours in the circles DEF, GKN, was the same as in the common halos, namely, red next the sun; and the diameter of the inner circle was also about 45°, which is the usual size of a halo.

Parhelia have been seen for one, two, three, and four hours together; and in North America they are said to continue some days, and to be visible from sun-rise to sun-set. When they disappear it sometimes rains, or snow falls in the form of oblong spiculæ.

Mr. Wales says, that at Churchill, in Hudson's-bay, the rising of the sun is always preceded by two long streams of red light. These rise as the sun rises; and, as they grow longer, begin to bend towards each other, till they meet directly over the sun, forming there a kind of parhelion, or mock sun.

These two streams of light, he says, seem to have their source in two other parhelia, which rise with the true sun; and in the winter season, when the sun never rises above the haze or fog which he says is constantly found near the horizon, all these accompany him the whole day, and set with him in the same manner as they rise. Once or twice he saw a fourth parhelion under the true sun; but this, he adds, is not common.

The cause of these is apparently the reflection of the sun's light and image from the thick and frozen clouds in the northern atmosphere, accompanied also with some degree of refraction. To enter upon a mathematical analysis of these phenomena would be only tedious, and very foreign to our purpose. From what has been said upon this subject it is evident, that all the phenomena of colours depend upon two properties of light, the refrangibility and reflexibility of its rays.

Of the inflection of light.—The direction of the rays of light is changed, as we have seen, in their approach to certain bodies, by reflection and refraction; and consequently we must admit that there is some power in these bodies by which such effects are universally produced. If reflection was produced simply by the impinging of particles of light on hard or elastic bodies, or if they were in themselves elastic, the same effects would follow as in the impulse of other elastic bodies; but the angle of incidence could not be equal to the angle of reflection, unless the particles of light were perfectly elastic, or the bodies on which they impinged were perfectly elastic. Now we know that the bodies on which these particles impinge are not perfectly elastic; and also that if the particles of light were perfectly elastic, the diffusion of light from the reflecting bodies would be very different from its present appearance: for as no body can be perfectly polished, the particles of light, which are so inconceivably small, would be reflected back by the inequalities on the surface in every direction; consequently we are led to this conclusion, that the reflecting bodies have a power which acts at some little distance from their surfaces.

If this reasoning is allowed to be just, it necessarily follows, that if a ray of light, instead of impinging on a body, should pass so near to it as to be within the sphere of that power which the body possesses, it must necessarily suffer a change in its direction. Actual experiments confirm the truth of this position; and to the change in the direction of a particle of light, owing to its nearness to a body, we give the name of inflection.

From one of these experiments, made by sir Isaac Newton, the whole of this subject will be easily understood. At the distance of two or three feet from the window of a darkened room, in which was a hole three-fourths of an inch broad, to admit the light, he placed a black sheet of pasteboard, having in the middle a hole about a quarter of an inch square, and behind the hole the blade of a sharp knife, to intercept a small part of the light which would otherwise have passed through the hole. The planes of the pasteboard and blade were parallel to each other; and when the pasteboard was removed at such a distance from the window, as that all the light coming into the room must pass through the hole in the pasteboard, he received what came through this hole on a piece of paper two or three feet beyond the knife, and perceived two streams of faint light shooting out both ways from the beam of light into the shadow. As the brightness of the direct rays obscured the fainter light, by making a hole in his paper he let them pass through, and had thus an opportunity of attending closely to the two streams, which were nearly equal in length, breadth, and quantity of light. That part which was nearest to the sun's direct light was pretty strong for the space of about a quarter of an inch, decreasing gradually till it became imperceptible; and at the edge of the knife it subtended an angle of about twelve, or, at most, fourteen degrees.

Another knife was then placed opposite to the former, and he observed, that when the distance of their edges was about the four-hundredth part of an inch, the stream divided in the middle, and left a shadow between the two parts, which was so dark, that all light passing between the knives seemed to be bent aside to one knife or the other; as the knives were brought nearer to each other, this shadow grew broader, till upon the contact of the knives the whole light disappeared.

Pursuing his observations upon this appearance, he perceived fringes, as they may be termed, of different-coloured light, three made on one side by the edge of one knife, and three on the other side by the edge of the other; and thence concluded, that as in refraction the rays of light are differently acted upon, so are they at a distance from bodies by inflection; and by many other experiments of the same kind he supported his position, which is confirmed by all subsequent experiments.

We may naturally conclude, that from this property of inflection some curious changes will be produced in the appearances of external objects. If we take a piece of wire of a less diameter than the pupil of the eye, and place it between the eye and a distant object, the latter will appear magnified (Plate III. fig. 21). Let A be a church-steeple, B the eye, C the wire. The rays by which the steeple would have been otherwise seen are intercepted by the wire; and it is now seen by inflected rays, which make a greater angle than the direct rays, and consequently the steeple will be magnified.

In nearly shutting the eyes, and looking at a candle, there appear rays of light extending from it in various directions, like comets' tails; for the light, in passing through the eye-lashes, is inflected; and consequently many separate beams will be formed, diverging from the luminous object. The power of bodies to inflect the rays of light passing near to them will produce different effects, according to the nature of the rays acted upon; consequently a separation will take place in the differently refrangible rays, and those fringes which were taken notice of by sir Isaac Newton will appear in other objects which are seen by the means of inflected rays. From considering thus the action of bodies upon light, we come to this general conclusion, for which we are indebted to our great philosopher: that light, as well as all other matter, is acted upon at a distance; and that reflection, refraction, and inflection, are owing to certain general laws in the particles of matter, which are equally necessary for the preservation of the beautiful harmony in the objects nearest to us, and to produce by their joint action that great law by which the greater bodies in their system are retained in their respective orbits.

OPTION. Every bishop, whether created or translated, is bound immediately after confirmation, to make a legal conveyance to the archbishop of the next avoidance of such dignity or benefice belonging to the see, as the said archbishop shall choose, which is therefore called an option.

OR, in heraldry, denotes yellow, or gold-colour. See HERALDRY.

ORANGE. See CITRUS.

ORBICULARIS. See ANATOMY.

ORBIT. See ASTRONOMY.

ORCHARD, a plantation of fruit-trees. In planting an orchard great care should be taken that the soil is suitable to the trees planted in it; and that they are procured from a soil nearly of the same kind, or rather poorer than that laid out for an orchard. As to the situation, an easy rising ground, open to the south-east, is to be preferred. Mr. Miller recommends planting the trees four-score feet asunder, but not in regular rows; and would have the ground between the trees plowed, and sown with wheat and other crops, in the same manner as if it was clear from trees; by which means the trees will be more vigorous and healthy, will abide much longer, and produce better fruit. If the ground has been pasture, the green sward should be plowed in the spring before the trees are planted; and if it is suffered to lie a summer fallow, it will greatly mend it, provided it is stirred two or three times to rot the grass, and prevent the growing of weeds. At Michaelmas it should be plowed pretty deep, in order to make it loose for the roots of the trees, which if the soil is dry, should be planted in October; but if it is moist, the beginning of March will be a better season. If several sorts of fruit-trees are to be planted on the same spot, you should observe to plant the largest-growing trees backwards, and so proceed to those of less growth, continuing the same method quite through the whole plantation; by which means the sun and air will more easily pass through the whole orchard. When you have planted the trees, you should support them with stakes, to prevent their being blown out of the ground by the wind; and the following spring, if the season should prove dry, cut a quantity of green turf, and lay it about the roots, with the grass downwards; by which means a great expence of watering will be saved, and after the first year they will be out of danger. Whenever you plow the ground betwixt these trees, you must be careful not to go too deep amongst their roots, which would greatly damage the trees; but if you do it cautiously, your stirring the face of the ground will be of great service to them: though you should observe, never to sow too near the tree, nor to suffer any great rooting weeds to grow about them; because this would starve them, by exhausting the goodness of the soil, which every two or three years should be mended with dung or other manure. These trees, after they are planted out, will require no other pruning besides cutting off their bad branches, or such as cross each other.

ORCHIS, *fool-stones*, a genus of the gynandria diandria class of plants, the corolla of which is of a corniculated form; and its fruit is an oblong unilocular capsule, containing numerous scobiform seeds.

The essential character is, nect. a horn or spur behind the flower. There are 50 species of this genus, which exceedingly resembles the ophrys. The most remarkable species are the following:

1. The mascula, or male fool-stones, has a root composed of two bulbs, crowned with oblong, broad, spotted leaves; upright stalks, a foot high, with one or two narrow amplexicaule leaves, and terminated by a long spike of reddish-purple flowers having the petals reflexed backward; a quadrilobed crenated lip to the nectarium, and an obtuse horn. The flowers of this species possess a very agreeable odour.

2. The morio, or female orchis, has a few amplexicaule leaves; and terminated by a short loose spike of flowers, having connivent petals, a quadrified crenated lip to the nectarium, and an obtuse horn.

3. The militaris, or man-orchis, has erect flower-stalks, eight or ten inches high, terminated by a loose spike of ash-coloured and reddish flowers, having confluent petals; a quinquefid, rough, spotted lip to the nectarium, and an obtuse horn. The structure of the flowers exhibits the figure of a naked man; and is often of different colours in the same flower, as ash-colour, red, brown, and dark-striped.

All the orchises are very hardy perennials, with bulbous fleshy roots. The flowers appear in May, June, and July, but principally in June: their mode of flowering is universally in spikes, many flowers in each spike; and each flower is composed of five petals in two series, and a nectarium. The season for removing them is in summer, after they have done flowering, when their leaves and stalks decay: plant them three inches deep, and let them remain undisturbed several years; for the less they are removed the stronger they will flower.

This plant flourishes in various parts of Europe and Asia, and grows in our country spontaneously, and in great abundance. It is assiduously cultivated in the East; and the root of it forms a considerable part of the diet of the inhabitants of Turkey, Persia, and Syria. From it is made the alimentary powder called salep; which, prepared from foreign roots, is sold at five or six shillings per pound, though it might be furnished by ourselves at a sixth part of that price, if we chose to pay any attention to the culture of this plant. The orchis mascula is the most valued for this purpose. A dry, and not very fertile soil, is best adapted to its growth.

The properest time for gathering the roots is when the seed is formed, and the stalk is ready to fall; because the new bulb, of which the salep is made, is then arrived to its full maturity, and may be distinguished from the old one, by a white bud rising from the top of it, which is the germ of the orchis of the succeeding year.

ORDEAL, a form of trial, or of discovering innocence or guilt, formerly practised over almost all Europe, and which prevailed in England from the time of Edward the Confessor, till it was abolished by a declaration of Henry III. It was called purgatio vulgaris, or judicium, in opposition to bellum, or combat, the other form of purgation.

In England an offender, on being arraigned, and pleading Not guilty, had it in his choice to put himself upon God and his country; that is, upon the verdict of a jury; or upon God alone, on which account it was called the judgment of God, it being presumed that God would deliver the innocent. The more popular kinds of ordeal were those of red-hot iron and water: the first for freemen and people of fashion, and the last for peasants. Fire ordeal was performed either by taking up in the hand a piece of red-hot iron, of one, two, or three pounds weight; or else by walking barefoot and blindfold over nine red-hot ploughshares, laid at unequal distances; and if the party escaped unhurt he was adjudged innocent, if not he was condemned as guilty. Water ordeal was performed either by plunging the bare arm up to the elbow in boiling water, and escaping unhurt thereby: or by casting the person suspected into a river or pond of water; and if he floated therein, without any action of swimming, it was deemed an evidence of his guilt; but if he sunk he was acquitted. 4 Black. 340.

ORDER. See ARCHITECTURE.

ORDERS, or ORDINATION. No person shall be admitted to the holy order of deacon under 23 years of age; nor to the order of priest unless he is 24 complete; and none shall be ordained without a title, that is, a nomination to some cure or benefice, and he shall have a testimonial of his good behaviour, for three years past, from three clergymen; and the bishop shall examine him, and if he sees cause may refuse him. And before he is ordained he shall take the oath of allegiance and supremacy before the ordinary, and subscribe the thirty-nine articles

ORDINARY, in common and canon law, is one who has ordinary or immediate jurisdiction in ecclesiastical causes in such a place. In which sense archdeacons are ordinaries, though the appellation is more frequently given to the bishop of the diocese, who has the ordinary ecclesiastical jurisdiction. The archbishop is the ordinary of the whole province, to visit and receive appeals from inferior judicatures.

ORDINATES, or ORDINATE APPLICATES, in geometry, are parallel lines, MM, *mm* (Plate Miscell. fig. 178), terminating in a curve, and bisected by a diameter, as AD. The half of these, as MP, *mp*, is properly the semiordinate, though commonly called ordinate.

ORDNANCE, a general name for all sorts of great guns used in war. See GUNNERY.

ORDNANCE, *boring of.* Guns are thus bored: the piece A (Plate Observatory, fig. 7.) is placed upon two standards BB, by means of two journeys, turned round by a water-wheel; the breech D being introduced into the central line of the wheel, with the muzzle towards the sliding carriage E, which is pressed forwards by a ratch F and weights. Upon this sliding carriage is fixed, truly horizontal and central to the gun, the drill-bar G, to the end of which is fixed a carp's tongue drill or cutter H; which, being pressed forward upon the piece whilst it is turning round, perforates the bore, which is afterwards finished with bars and cutters.

The machinery for boring of ordnance is sometimes put in motion by a steam-engine: and in this way, from 18 to 24 great guns have been boring at the same time; the borer in each piece being brought up to its proper place in the gun, by a lever and weights. In this method of bringing up the borer the pressure may always be made equable, and the motion of the borer regular; but the disadvantage is, that without due attention the borer may work up too far towards the breech, and the piece be spoiled. In the royal arsenal at Woolwich, only one piece is bored at a time in the same mill: the gun to be bored lies with its axis parallel to the horizon, and in that position is turned round its axis by means of wheel-work, moved by one or more horses. The borer is laid, as above described, in the direction of the axis of the gun, and is incapable of motion in any direction except that of its length; and in this direction it is constantly moved by means of a small rack-wheel, kept in proper motion by two men, who thus make the point of the borer so to bear against the part of the gun that is boring, as to pierce and cut it. The outside of the gun is smoothed at the same time by men with instruments fit for the purpose, whilst it turns round, so that the bore may be exactly in the centre of the metal. See Gregory's Mechanics.

ORDNANCE, *office of*, an office kept within the Tower of London, which superintends and disposes of all the arms, instruments, and utensils of war, both by sea and land, in all the magazines, garrisons, and forts, in Great Britain.

ORES, METALLIC. This class comprehends all the mineral bodies, composed either entirely of metals, or of which metals constitute the most considerable and important part. It is from the minerals belonging to this class that all metals are extracted; for this reason they have obtained the name of ores.

As the metals at present known amount to 23, we shall divide this class into 23 orders, allotting a distinct order for the ores of every particular metal.

Metals exist in ores in one or other of the four following states: 1. In a metallic state, and either solitary, or combined with each other. 2. Combined with sulphur. 3. In the state of oxides. 4. Combined with acids. Each order therefore may be divided into the four following genera:

1. Alloys. 3. Oxides.
2. Sulphurets. 4. Salts.

It must be observed, however, that every metal has not hitherto been found in all these four states, and that some of them are hardly susceptible of them all. Some of the orders, therefore, want one or more genera, as may be seen from the following table, taken from Dr. Thomson's incomparable work on chemistry; a work of which every student of that science, or of natural philosophy, ought to be possessed.

ORDER I. *Gold.*
1. Alloys.

ORDER II. *Platinum.*
1. Alloys.

ORDER III. *Silver.*
1. Alloys.
2. Sulphurets.
3. Oxides.
4. Salts.

ORDER IV. *Mercury.*
1. Alloys.
2. Sulphurets.
3. Oxides.
4. Salts.

ORDER V. *Copper.*
1. Alloys.
2. Sulphurets.
3. Oxides.
4. Salts.

ORDER VI. *Iron.*
1. Alloys.
2. Sulphurets.
3. Oxides.
4. Salts.

ORDER VII. *Tin.*
1. Sulphurets.
2. Oxides.

ORDER VIII. *Lead.*
1. Sulphurets.
2. Oxides.
3. Salts.

ORDER IX. *Nickel.*
1. Sulphurets.
2. Oxides.

ORDER X. *Zinc.*
1. Sulphurets.
2. Oxides.
3. Salts.

ORDER XI. *Antimony.*
1. Alloys.
2. Sulphurets.
3. Oxides.
4. Salts.

ORDER XII. *Bismuth.*
1. Alloys.
2. Sulphurets.
3. Oxides.

ORDER XIII. *Tellurium.*
1. Alloys.

ORDER XIV. *Arsenic.*
1. Alloys.
2. Sulphurets.
3. Oxides.
4. Salts.

ORDER XV. *Cobalt.*
1. Alloys.
2. Sulphurets.
3. Oxides.
4. Salts.

ORDER XVI. *Manganese.*
1. Oxides.
2. Salts.

ORDER XVII. *Tungsten.*
1. Oxides.

ORDER XVIII. *Molybdenum.*
1. Sulphurets.

ORDER XIX. *Uranium.*
1. Oxides.

ORDER XX. *Titanium.*
1. Oxides.

ORDER XXI. *Chromium.*
1. Oxides.

ORDER XXII. *Columbium.*
1. Alloys.

ORDER XXIII. *Tantalium.*
1. Oxides.

ORES, *analysis of.* The diversity of metallic ores is so great, that no general method of analysis can be given. We shall therefore follow the different orders, and point out the proper method of analysing each. In the rules we shall follow Bergman, to whom we are indebted for the first precise treatise on the analysis of ores, except when his methods have been superseded by the improvements of succeeding chemists.

Gold ores. The presence of gold may easily be detected by treating the mineral supposed to contain it with nitro-muriatic acid, and dropping muriat of tin into the solution. If the solution contains any gold, a purple precipitate immediately appears.

Native gold ought to be dissolved in nitro-muriatic acid: the silver, if any is present, falls to the bottom in the state of muriat, and may be separated by filtration, and weighed. Pour sulphat of iron into the solution, and the gold is precipitated in the metallic state. The copper, if any is present, may be precipitated by means of a plate of iron. The presence of iron may be ascertained by dropping tincture of nutgalls into a portion of the solution.

The auriferous pyrites may be treated with diluted nitrous acid, which dissolves the iron, and separates the sulphur. The gold remains insoluble, and is found in the state of small grains.

Ores of platinum. Proust's method is, first to separate the sand with which the grains of platinum are mixed, by exposing them to a blast of air. By heat he evaporates the mercury, which still adheres to them, and then picks out the grains of gold, which are always mixed with platinum, and which are thus rendered visible. The ore is then dissolved in an acid composed of one part of nitre and three parts of muriatic acid. A black powder remains. This powder, when roasted, gives out phosphorus and sulphur. After this it is dissolved by nitro-muriatic acid, except a small residuum, which is plumbago. The solutions are then to be mixed. They consist of muriats of platinum, and oxymuriats of copper and iron. By evaporating till the liquid when cold assumes a consistency greater than honey, and inclining the retort, the oxymuriats run off, and leave the muriat of platinum, which may be obtained pure by repeated solutions and crystallizations. The solution containing the muriats, and perhaps also a little platinum, is to be diluted with a great proportion of water; and pure ammonia dropt in. The red oxide of iron precipitates, and may be estimated by weighing it. When the solution is somewhat concentrated, ammonia precipitates the platinum in the state of a triple salt; and the copper, which now only remains, may be precipitated by a plate of iron.

Ores of silver. The analysis of the ores of silver has been always considered as very important, on account of the great value of the metal which they contain in greatest abundance.

1. Native silver is to be dissolved in nitric acid. The gold, if the ore contains any, remains in the state of a black powder, and may be dried and weighed. The silver may be precipitated by common salt. One hundred parts of the precipitate dried denote about seventy-five parts of silver. The presence of copper may be ascertained by the greenish-blue colour of the solution, and by the deep-blue colour which it assumes on adding ammonia. The copper may be precipitated by a plate of iron, or by the rules laid down hereafter. When the ore contains arsenic, its proportion may be estimated by weighing before and after fusion; for the arsenic is dissipated by heat, or the ore may be dissolved as before in nitric acid, which acidifies the arsenic. After the separation of the silver, the arsenic acid may be precipitated by nitrat of lead, 100 parts of the dry precipitate indicating about 22 of arsenic.

2. Alloy of silver and antimony is to be treated with nitric acid, which dissolves the silver, and oxidizes the antimony. The silver is estimated as above. The oxide of antimony may be reduced by fusion with four times its weight of black flux and a little soap.

3. Sulphuret of silver is to be treated with diluted nitric acid, which dissolves the silver, leaving the greater part of the sulphur untouched. The residuum is to be dried, and then the sulphur burnt off. The loss of weight gives the sulphur. The residuum, if any, is undecomposed sulphuret, to be treated as at first. The silver is to be precipitated by common salt; and the other metals, if any are present, may be ascertained as above. Part of the sulphur is always acidified. The acid thus formed may be precipitated by nitrat of barytes, 100 parts of the dried precipitate indicating about 14.5 of sulphur.

4. Antimoniated silver ore was analysed by Klaproth in the following manner: 100 parts of it were boiled in diluted nitric acid. The residuum, washed and dried, was 26. These 26 were digested into nitro-muriatic acid. The residuum now weighed 13 (so that 13 had been dissolved), 12 of which were sulphur, and burnt away, leaving behind them one part of silica. The nitro-muriatic solution, when diluted largely with water, let fall a precipitate which weighed 13 (or 10 of pure antimony), and had the properties of oxide of antimony; for they did not evaporate till heated to redness, but at that temperature were dissipated in a grey smoke.

The nitric solution was green. Common salt occasioned a precipitate which weighed 87.75, equivalent to 65.81 of pure silver. After the separation of this muriat of silver, sulphat of soda occasioned no precipitate. Therefore the solution contained no lead. When supersaturated with soda, a grey precipitate fell, weighing five parts. On burning coals this precipitate gave out an arsenical smell. It was redissolved in nitric acid; sulphurated alkali occasioned a smutty brown precipitate; and prussic alkali a Prussian blue, which after torrefaction was magnetic. Hence he concluded, that these five parts were a combination of iron and arsenic acid.

The nitric solution which had been supersaturated with ammonia was blue; he therefore suspected that it contained copper. To discover this, he saturated it with sulphuric acid, and put it into a polished plate of iron. The quantity of copper was so small, that none could be collected on the iron.

5. Sulphuret of silver and copper may be analysed as No. 3. separating the copper by means of a plate of iron.

6. Black silver ore may be analysed as No. 2. separating the copper, if any is present, by means of an iron plate, and estimating the carbonic acid that escapes when the ore is heated or dissolved in nitric acid.

7. Red silver was analysed by Vauquelin in the following manner: one hundred parts of it were digested in 500 parts of nitric acid previously diluted with water. The undissolved residuum, being washed and dried, weighed 42.06. Being treated with muriatic acid, it was all dissolved except 14.66 parts, which were sulphur. The muriatic solution, when diluted with a great quantity of water, deposited a white powder, which weighed 21.25, and was oxide of antimony. The nitric acid solution remained still to be examined. Muriatic acid occasioned a heavy precipitate, which weighed 72.66 parts, and which was muriat of silver. Reagents shewed that the acid retained no other substance of solution.

8. Muriat of silver was analysed by Klaproth: one hundred parts of it were mixed with thrice their weight of pure carbonat of potass, and melted together in a glass retort. The mass was dissolved in water, and the solution filtred. A residuum remained, which was dissolved in nitric acid, with the exception of a red powder, which, treated with nitro-muriatic acid, was dissolved, except a little muriat of silver, which, when reduced, yielded .5 of pure silver. Ammonia precipitated from the nitro-muriatic solution 2.5 parts of oxide of iron. The nitric solution was precipitated by common salt; the muriat of silver, thus obtained, yielded, when reduced, 67.25 of pure silver.

The original aqueous solution of the alkaline mass was saturated with acetous acid, on which it deposited 1.75 parts of alumina. The solution was evaporated to dryness, and the dry mass treated with alcohol, which dissolved the acetite of potass. The residuum, amounting to 58.75 parts, was dissolved in water, and being treated with muriat of barytes, 15 parts of sulphat of barytes precipitated, indicating the presence of about .5 of sulphuric acid, or 0.75 sulphat of potass. The remaining 58 parts were muriat of potass, indicating about 21 parts of muriatic acid.

Ores of mercury. We have very few exact analyses of the ores of mercury, owing, perhaps to the facility with which the mercury is extracted from them by distillation.

Native mercury and amalgam may be dissolved in nitric acid. The gold, if any is present, remains in the state of powder, and may be estimated by its weight. The affusion of water precipitates the bismuth, if the solution happens to contain any. Common salt precipitates the silver, and also part of the mercury; but the latter may be redissolved by a sufficient quantity of water, or, which is far better, of oxymuriatic acid, while the muriat of silver remains insoluble. Lastly, the mercury may be precipitated by sulphat of iron, and estimated.

2. Native cinnabar may be treated with a mixture of three parts muriatic and one part nitric acid, which dissolves the mercury, and leaves the sulphur. The mercury may be estimated as in the last paragraph.

3. Hepatic mercurial ore has not been analysed. Its analysis may be attempted as in No. 2. or by dissolving it in nitric acid.

4. Muriat of mercury may be digested in muriatic acid till the whole is dissolved. Muriat of barytes precipitates the sulphuric acid, 100 parts of which are equivalent to 186 of sulphat of mercury; and the proportion of this salt being known, we have that of the muriat.

Ores of copper. Native copper sometimes contains gold, silver, or iron. It may be dissolved in nitric acid; the gold remains in the state of a blackish or rather violet-coloured powder; the silver may be separated by a polished plate of copper (or it may be precipitated from a separate portion of the solution by common salt); the iron may be separated by boiling the solution to dryness, and treating the residuum with water. By this process, the nitrat of iron is decomposed; the oxide of iron remains, while the water dissolves the nitrat of copper. This last salt may be decomposed by boiling it with potass; the precipitate dried in a red heat, is black oxide of copper. One hundred parts of it denote 80 of metallic copper.

2. Sulphuret of copper may be dissolved in diluted nitric acid. Part of the sulphur remains unaltered, and may be estimated by weighing it, and burning it off. Part is acidified, and may be precipitated by nitrat of barytes; 100 parts of the dried precipitate indicating 14.5 of sulphur. By evaporation to dryness, and solution in water, the iron is separated; and the copper may be estimated as in the last paragraph; or muriatic acid may be used instead of nitric; but in that case it is more difficult to obtain a complete solution.

3. Grey copper ore was analysed by Klaproth in the following manner: three hundred parts of it were digested with four times their weight of nitric acid. This operation was repeated, and the two acid liquids mixed. The undissolved residuum was 188 parts. The nitric solution was green, and when common salt was added to it, muriat of silver precipitated. The solution being now supersaturated with ammonia, 9.5 parts of a fleaky red precipitate were obtained, which was found to be composed of silica, alumina, and iron, by dissolving it in muriatic acid, and proceeding by the rules laid down in the first section. A polished iron plate precipitated from the nitric solution 69 parts of copper.

The 188 parts of residuum were boiled with six times their weight of muriatic acid; 105.5 parts remained undissolved, which were sulphur and silica. The muriatic acid solution being concentrated, yielded a little muriat of silver. Being diluted with a large portion of water, a white powder precipitated, which weighed 97.5 parts, and was oxide of antimony.

4. Red copper ore has only to be dissolved in muriatic acid, and the copper precipitated by a plate of iron; 88 parts of the precipitated copper being equivalent to 100 of the orange oxide of which the ore is composed.

5. The analysis of the oxides and carbonats of copper scarcely requires any remarks. The water and carbonic acid must be estimated by distillation in close vessels, and collecting the products. The ore may then be dissolved in nitric acid, and its copper ascertained as above.

6. Arseniat of copper was analysed by Mr. Chenevix, in the following manner: the ore was dissolved in diluted nitric acid, and nitrat of lead poured in. The solution was evaporated till a precipitate began to appear, and then mixed with alcohol. Arseniat of lead precipitated. One hundred parts of this salt indicate 33 of arsenic acid. The copper was separated from the nitric acid by boiling it with potass.

Ores of iron. Notwithstanding the great variety of iron ores, they may be all, as far as analysis is concerned, arranged under three heads; namely, 1. Sulphurets; 2. Oxides; and 3. Salts.

1. Pyrites, or sulphureted iron, may be treated repeatedly with boiling nitric acid till the sulphur is acidified. Muriatic acid is then to be added, and the digestion continued till the whole is dissolved. Muriat of barytes is then to be added to precipitate the sulphuric acid; 100 of the dried precipitate indicate 14.5 of sulphur. If the solution contains only iron, it may be precipitated by carbonat of soda, calcined to redness, and weighed. But if earths or manganese are present, we must proceed by the rules laid down in the first section.

2. If the oxides of iron are pure, that is, contain nothing but iron, we have only to dissolve them in muriatic acid, and precipitate them as above. But it is very seldom that ores possess this perfect degree of purity. The iron is usually combined with manganese, alumina, silica, or with all of these together. The analysis is to be conducted exactly according to the rules already laid down.

3. The sparry iron ore may be analysed in the same manner, excepting only that the carbonic acid gas must be separated by distillation or solution in close vessels.

4. Arseniat of iron was analysed by Mr. Chenevix in the following manner: One hundred parts of it were boiled with potass till the arsenic acid was separated. Nitrat of lead was mixed with the solution; 100 parts of the precepitate indicated 33 of arsenic acid. That portion of the ore which eluded the action of the potass was treated with muriatic acid; the undissolved residuum was silica. The muriatic acid was supersaturated with ammonia. The iron precipitated; but the copper was dissolved by the ammonia.

Ores of tin. 1. The sulphuret of tin was thus analysed by Klaproth: 120 parts of the ore were digested with nitro-muriatic acid; 43 parts remained undissolved. Of these, 30 burnt away with a blue flame, and were sulphur; of the remaining 13, eight dissolved in nitro-muriatic acid. The undissolved five were heated with wax, and yielded a grain of iron attracted by the magnet. The rest was a mixture of alumina and silica. The nitro-muriatic solution was completely precipitated by potass, and the precipitate redissolved in muriatic acid. A cylinder of tin precipitated 44 parts of copper from this solution, and lost itself 89 parts of its weight. A cylinder of zinc precipitated 130 parts of tin; so that, deducting the 89 parts of tin dissolved during the precipitation of the copper, 41 remain for the tin contained in the ore.

2. Tin stone was thus analysed: One hundred parts of the ore were heated to redness, with 600 parts of potass, in a silver crucible; and the mixture being treated with warm water, 11 parts remained undissolved. These 11, by a repetition of the treatment with potass, were reduced to $1\frac{1}{4}$th. This small residuum dissolved in muriatic acid. Zinc precipitated from the solution one-half part of tin, and the Prussian alkali gave a blue precipitate, which indicated one-fourth part of iron.

The alkaline solution was saturated with muriatic acid; a white precipitate appeared, but it was redissolved by adding more acid. The whole was precipitated by carbonat of soda. The solution, which had a yellowish colour, was redissolved in muriatic acid; and a cylinder of zinc being inserted into the solution, 77 of tin were obtained, indicating nearly 98 parts of oxide of tin.

Ores of lead. 1. Sulphuret of lead usually contains a little silver, and sometimes also antimony and zinc. It may be treated with diluted nitric acid, which leaves only the sulphur undissolved, the weight of which is to be taken, and its purity determined by combustion. If antimony is present, it will either remain in the state of a white oxide, or if dissolved, it will be precipitated by diluting the solution with water. Muriatic acid is to be added, and the solution evaporated till it is reduced to a small portion. Muriat of lead and of silver precipitate. The first of these may be dissolved in boiling water, the second remains insoluble. Westrum separated the muriat of silver by digesting the precipitate with ammonia. The liquid from which the muriats were separated may contain iron, zinc, copper. The iron may be precipitated by ammonia added in excess; the copper, by a plate of zinc; the zinc may be precipitated by carbonat of soda reduced to the metallic state, and weighed; subtracting what had been separated from the plate of zinc.

2. Arseniated peroxide of lead was thus analysed by Vauquelin: 100 parts roasted for half an hour, and occasionally treated with a little tallow, lost 38 parts, which were considered as oxide of arsenic. The residue was treated with concentrated muriatic acid, and boiled in it for a quarter of an hour. The liquid assumed a red colour, and emitted abundance of oxymuriatic acid gas. A white needleform salt was deposited, and some of it was obtained by evaporation. This salt, dissolved in water, and treated with sulphat

of soda, yielded 25 parts of sulphat of lead, = 20.2 parts of lead. The liquor thus freed from lead was treated with ammonia. The precipitate obtained weighed 39 parts. It consisted of oxide of iron mixed with oxide of arsenic. The production of oxymuriatic acid induced Vauquelin to consider the lead as in the state of peroxide.

3. Carbonat of lead was thus analysed: One hundred grains were thrown into 200 grains of nitric acid diluted with 300 grains of water. It dissolved completely with effervescence. The loss of weight was 16 grains. It was equivalent to the carbonic acid. The solution, which was colourless, was diluted with water, and a cylinder of zinc put into it. In 24 hours the lead was precipitated in the metallic state. It weighed 77 grains, = 82 grains oxide. If muriatic acid is suspected, it may be easily detected, and its weight ascertained, by means of nitrat of silver.

4. Sulphat of lead was thus analysed by Klaproth: One hundred grains of the ore, heated to redness, lost two grains, which were considered as water. It was then mixed with 400 grains of carbonat of potass, and heated to redness in a platinum crucible. The reddish yellow mass thus obtained was digested in water, and the whole thrown on a filtre. The oxide of lead thus obtained weighed 72 grains. It was dissolved in diluted nitric acid. One grain of oxide of iron remained behind. Into the solution a cylinder of zinc was put. The lead thrown down weighed $66\frac{1}{2}$ grains. The alkaline solution was supersaturated with nitric acid, and then treated with acetat of barytes. The sulphat of barytes obtained weighed 73 grains, which Klaproth considers as indicating 25 grains of sulphuric acid.

5. Phosphat of lead was thus analysed: One hundred grains were dissolved in diluted nitric acid. Nitrat of silver dropt into the solution formed a precipitate weighing 11 grains, = 1.7 grains muriatic acid. The solution was mixed with sulphuric acid. The sulphat of lead precipitated weighed 106 grains, = 78.4 oxide of lead. The solution was freed from sulphuric acid by means of nitrat of barytes, and then almost neutralized with ammonia. Acetat of lead was then dropt in. The phosphat of lead which precipitated weighed 82 grains, = 18.37 phosphoric acid. The solution was now mixed with muriatic acid, evaporated to dryness, and the dry mass washed in alcohol. The alcohol, when evaporated, left a small residue, which dissolved in water, and formed Prussian blue with prussiat of potass. It contained about $\frac{1}{10}$ grain of oxide of iron.

6. Molybdat of lead was thus analysed by Mr. Hatchet. The ore was boiled repeatedly with sulphuric acid till the acid refused to dissolve any more. The solution contained the molybdic acid. The undissolved powder (sulphat of lead) was boiled for an hour with carbonat of soda, and then washed. Nitric acid now dissolved it, except a little silica. The lead was precipitated from this solution by sulphuric acid; after which ammonia separated a little oxide of iron. The sulphuric acid solution was diluted with 16 parts of water, and saturated with ammonia; a little oxide of iron gradually precipitated. The solution was now evaporated to dryness, and the mass strongly heated to separate the sulphat of ammonia. The residuum repeatedly treated with nitric acid was converted into yellow molybdic acid.

Ores of nickel. Kupfer nickel may be dissolved in nitric acid, by which the greatest part of the sulphur will be separated. The arsenic may be afterwards precipitated by the affusion of water. A plate of iron will expel the copper, if any should be present. Precipitate by potass added in excess, and boil the precipitate, which will separate the arsenic and sulphur completely. Dissolve the precipitate (previously exposed moist for some time to the air) in acetic acid, and add an excess of ammonia. The iron is precipitated; but the cobalt and nickel remain in solution. Evaporate, and the cobalt is deposited; then by continuing the evaporation to dryness the nickel is obtained.

Ores of zinc. 1. Blende may be treated with diluted nitric acid, which will separate the sulphur, the siliceous gangue, &c. The purity of the sulphur is to be ascertained by combustion, and the residuum analysed in the manner formerly described. Precipitate the nitric solution by soda, redissolve in muriatic acid, precipitate the copper (if any should be present) by a plate of iron; separate the iron by adding an excess of ammonia. The zinc now only remains in the solution, which may be obtained by evaporating to dryness, redissolving in muriatic acid, and precipitating by soda.

2. Calamine may be digested in nitric acid, noting the loss of weight for carbonic acid, and the insoluble residuum boiled with muriatic acid repeatedly; what remains after dilution with boiling water is silica. The nitric solution contains zinc, and probably also iron and alumina; evaporate to dryness, redissolve, and add an excess of ammonia. The iron and alumina either remain undissolved or are precipitated, and they may be separated by potass. The zinc may be precipitated by an acid, or by evaporation to dryness. The muriatic solution probably contains iron and alumina, which may be precipitated by the rules already laid down.

Ores of antimony. Native antimony was thus analysed: One hundred grains were digested in nitric acid till the whole was converted into a white powder. When the acid emitted no longer any nitrous gas, the mixture was diluted with water and thrown upon a filtre. The solution was then treated with nitrat of silver. The precipitate yielded by reduction one grain of silver. The prussiat of potass threw down from the residuum solution a precipitate which contained $\frac{1}{4}$ grain of iron. The white oxide formed by the nitric acid was digested in muriatic acid; the whole dissolved and formed a transparent solution. It was diluted with six times its weight of water, and the precipitate redissolved in muriatic acid, and a cylinder of zinc put into it. The antimony obtained weighed 98 grains.

2. Sulphuret of antimony is to be treated with nitro-muriatic acid. The sulphur and the muriat of silver (if any silver is present) will remain. Water precipitates the antimony; sulphuric acid, the lead; and ammonia the iron.

3. Klaproth analysed the red ore of antimony as follows: One hundred grains were digested in muriatic acid till the whole dissolved, except $1\frac{1}{2}$ grains of sulphur. A little sulphuret of antimony rose with the sulphureted hydrogen gas exhaled, and was deposited in the beak of the retort. The solution was diluted with water. The whole precipitated in the state of a white powder; for potass threw nothing from the liquid. The powder was redissolved in muriatic acid, an excess added, and the solution diluted. A plate of iron threw down $67\frac{1}{2}$ grains of antimony. The ore then contained 78.3 grains of oxide of antimony. One hundred grains of the ore yielded by solution in muriatic acid 37 cubic inches of sulphureted hydrogen gas. From this, Klaproth concluded that it contained 20 grains of sulphur.

Ores of bismuth. Native bismuth may be treated with nitric acid. Repeated concentrations and affusions of water precipitate the bismuth, and perhaps the arsenic; but this last may be redissolved in boiling water. The cobalt remains, and may be examined by the rules to be hereafter laid down. The same analysis succeeds with the other ores of bismuth. The sulphur when present remains undissolved.

We shall give as an example of these ores Klaproth's analysis of a sulphuret of bismuth. Fifty grains of the ore were digested in nitric acid. The whole was dissolved except $2\frac{1}{2}$ grains of sulphur. The solution being diluted with water, a white powder precipitated. The filtred solution was treated with common salt; at first it produced no change, but by and by the whole became milky. The precipitate consisted, like the last, of oxide of bismuth. The solution continuing clear for some time, indicated that no silver was present. The white precipitate was not altered by exposure to the light; an additional proof that no silver was present.

Ores of tellurium. Klaproth dissolved the white gold ore of Fatzbay in nitro-muriatic acid, and added potass in excess to the solution. A brown precipitate remained undissolved, which was a mixture of gold and iron. It was redissolved in nitro-muriatic acid, the gold first precipitated by nitrat of mercury, and then the iron by potass. The potass in the first solution being saturated with muriatic acid, the oxide of tellurium precipitated.

The other ores may be analysed in the same manner; only the precipitate occasioned by the potass must be treated according to the metals of which it consists. The rules have been already laid down.

Ores of arsenic. Native arsenic may be treated with nitro-muriatic acid. The silver and gold remain; the first in the state of a muriat; the second may be dissolved by means of nitro-muriatic acid, and precipitated by sulphat of iron. The arsenic may be precipitated by concentrating the nitric solution, and then diluting with water. The iron may then be precipitated by ammonia.

2. The sulphureted ores of arsenic may likewise be treated with diluted nitro-muriatic acid. The sulphur remains undissolved; the arsenic may be precipitated by concentration and the affusion of water; the iron by ammonia.

3. Oxide of arsenic may be dissolved in sixteen parts of water. The solution displays acid properties, and nitrat of silver and of mercury occasion precipitates in it.

Ores of cobalt. White cobalt ore was thus analysed by Tassaert. To ascertain the proportion of arsenic he treated the ore with diluted nitric acid, and obtained a complete solution. Crystals of white oxide of arsenic were deposited, and by repeated evaporations he separated the whole of the arsenic, and ascertained its weight. He then boiled a new portion of the ore with four times its weight of nitric acid, and thus acidified the arsenic, and obtained a solution. This solution was treated with potass, which retained the arsenic acid, and separated the other bodies. A precipitate of arseniat of cobalt, which had fallen when the nitric solution was diluted with water, was treated with potass for the same reason. The residuum, together with the precipitate occasioned by the potass, was dissolved in nitric acid, and ammonia added in excess. Part was retained in solution by the ammonia; but part was precipitated. The precipitate was dissolved in acetic acid, and the solution repeatedly evaporated to dryness. By this process the oxide of iron gradually separated in the form of a red powder. The dissolved part was acetat of cobalt. It was decomposed by the addition of ammonia in excess, which redissolved the cobalt. By these processes the arsenic and iron were separated; the cobalt was retained by the ammonia, and was obtained by evaporation. To ascertain the proportion of sulphur in the ore a new portion was boiled with nitric acid. On cooling, crystals of white oxide of arsenic were deposited. These being separated, nitrat of barytes was added to the solution; 100 parts of the dried precipitate indicated 14.5 of sulphur.

The other ores of cobalt may be analysed nearly in the same way.

Ores of manganese. 1. Barytated manganese was treated by Vauquelin with muriatic acid; oxymuriatic gas passed over, and the whole was dissolved except a little charcoal and silica. The solution when evaporated yielded crystals of muriat of barytes. These were separated; and the liquid, evaporated to dryness, yielded a yellow mass soluble in alcohol, and tinging its flame with yellow brilliant sparks. The proportion of barytes was ascertained by precipitating it in the state of a sulphat; the manganese, by precipitating it by carbonat of potass.

2. The grey ore of manganese was treated by the same chemist with muriatic acid; some silica remained undissolved. Carbonat of potass was added to the solution. The precipitate was at first white, but became black when exposed to the air. It was treated with nitric acid, which dissolved every thing but the manganese and iron (if any had been present). The nitric solution, when mixed with carbonat of potass, deposited only carbonat of lime. The black residuum was mixed with sugar, and treated with nitric acid. The solution was complete; therefore no iron was present.

The same processes will succeed with the other ores of manganese. When iron is present, it may be separated either as above, or by the rules laid down in the first section; or what succeeds better, we may dissolve the mixture in acetic acid, and evaporate to dryness two or three times repeatedly. The oxide of iron is left behind, while the acetat of manganese continues soluble in water.

Ores of tungsten. Wolfram was analysed nearly as follows: The ore was boiled with muriatic acid, and then digested with ammonia alternately till the whole was dissolved. The ammoniacal solutions being evaporated to dryness and calcined, left the yellow oxide of tungsten in a state of purity. The muriatic solutions were mixed with sulphuric acid, evaporated to dryness, and the residuum redissolved in water. A little silica remained. Carbonat of potass precipitated a brown powder from this solution. This powder was treated with boiling nitric acid repeatedly, till the iron which it contained was oxidized to a maximum. It was then digested in acetic acid, which dissolved the manganese, and left the iron. Finally, the manganese was precipitated by an alkali.

Tungstat of lime was thus analysed by Klaproth: One hundred grains of it were digested in nitric acid. The yellow-coloured residue was washed and digested in ammonia. The residue was digested in nitric acid and ammonia alternately, till a complete solution was obtained. Two grains of silica remained behind. The nitric acid solution was mixed with ammonia, but no precipitate appeared. It was then mixed with a boiling solution of carbonat of soda. The precipitate dried weighed 33 grains. It was carbonat of lime; but when redissolved in nitric acid, it left one grain of silica. Thirty-two grains of carbonat are equivalent to 17.6 of lime. The ammoniacal solution, by evaporation, yielded small needleform crystals. When heated to redness in a platinum cruible, they left $77\frac{3}{4}$ grains of oxide of tungsten.

Ores of molybdenum. Molybdena may be treated with nitric acid successively boiled upon it till it is converted into a white powder. This powder, washed and dried, is molybdic acid. The liquid obtained by washing the acid, on the addition of potass, deposits some more molybdic acid. This being separated, muriat of barytes is to be dropt into it as long as any precipitate appears. One hundred parts of this precipitate indicate 14.5 of sulphur.

Ores of uranium. 1. Pechblende, or the black ore of uranium, was dissolved by Klaproth in nitric acid. The undissolved part is a mixture of silica and sulphur. By evaporating the solution, nitrat of lead was precipitated; then nitrated uranium in crystals. The solution being now evaporated to dryness, and treated again with nitric acid, left the iron in the state of red oxide.

2. Uranitic ochre may be treated with nitric acid, which dissolves the uranium, and leaves the iron. The purity of the iron may be tried by the rules already laid down.

3. Green mica was dissolved by Klaproth in nitric acid, and ammonia added in excess to the solution. The oxide of uranium was precipitated; that of copper retained.

Ores of titanium. The ores of titanium, reduced as usual to a fine powder, are to be fused with potass or its carbonat. The melted mass is then to be dissolved in hot water. A white precipitate gradually separates, which is the white oxide of titanium. This is all that is necessary to analyse the first species. But when iron and silica are present, the following method of Chenevix may be adopted: Saturate the alkaline solution with muriatic acid. White oxide of titanium precipitates. Separate the precipitate, and evaporate the solution to dryness. Redissolve the residuum in water. The silica remains behind. Precipitate the solution by an alkali; add the precipitate to the white oxide obtained at first, and dissolve the whole in sulphuric acid. From this solution phosphoric acid precipitates the titanium, but leaves the iron.

The third species, which contains lime and no iron, is to be fused with potass, dissolved in muriatic acid, and the silica separated in the usual way. After this the titanium is first to be separated from the muriatic solution by ammonia; and afterwards the lime by an alkaline carbonat.

Ores of chromium. Vauquelin analysed the chromat of lead in the following manner: When boiled with a sufficient quantity of carbonat of potass, a lively effervescence takes place; the acid combines with the potass, and the carbonat of lead is formed, and remains undissolved. It may be dissolved in nitric acid, and its quantity ascertained by precipitation with sulphuric acid. Or the chromat may be treated with muriatic acid; muriat of lead precipitates, and chromic acid remains in solution. This process must be repeated till the whole of the ore is decomposed. There remains in solution chromic acid mixed with a little muriatic, which may be separated by means of oxide of silver.

ORGAN, in general, is an instrument or machine designed for the production of some certain action or operation; in which sense the mechanic powers, machines, and even the veins, arteries, nerves, muscles, and bones of the human body, may be called organs.

The organs of sense are those parts of the body by which we receive the impressions or ideas of external objects, being commonly reckoned five, viz. the eye, ear, nose, palate, and cutis.

ORGAN, a wind-instrument blown by bellows, and containing numerous pipes of various kinds and dimensions, and multifarious tones and powers. Of all musical insruments this is the most proper for the sacred purpose to which it is most generally applied in all countries wherever it has been introduced. Its structure is lofty, elegant, and majestic; and its solemnity, grandeur, and rich volume of tone, have justly obtained it an acknowledged pre-eminence over every other instrument.

An organ, when complete, is of threefold construction, and furnished with three sets of keys; one for what is called the great organ, and which is the middle set; a second (or lower set) for the choir organ; and a third (or upper set) for the swell. In the great organ, the principal stops are the two diapasons, the principal, the twelfth, the fifteenth, the sesquialtra, the mixture or furniture, the trumpet, the clarion, and the cornet. The choir organ usually contains the stopt diapason, the dulciana, the principal, the flute, the twelfth, the bassoon, and the vox humana. The swell comprises the two diapasons, the principal, the hautboy, trumpet, and cornet. Besides the complete organ, there are other organs of lesser sizes, and more limited powers, adapted to church, chapel, and chamber use. There is also the barrel or hand organ, consisting of a moveable turning cylinder called a barrel, on which, by means of wires, pins, and staples, are set the tunes it is intended to perform. These pins and staples, by the revolution of the barrel, act upon the keys within, and give admission to the wind from the bellows to the pipes. The barrel organ is generally portable; and so contrived that the same action of the hand which turns the barrel, supplies the wind by giving motion to the bellows.

The invention of the organ, which is attributed to the Greeks, is very antient, though it is generally allowed to have been little used before the eighteenth century.

It has been a subject of debate at what time the use of organs was first introduced into the church. Some writers say, that they were first applied to sacred use in the time of pope Vitalian, about the year 660; others that they were not employed in that way till the ninth century. A learned author has, however, shewn that neither of these dates can be just: and Thomas Aquinas expressly says, that in his time (about the year 1250) the church did not use musical instruments; and Bingham says, that Marinus Sauntus, who lived about the year 1290, first introduced the use of them into churches. But if we may give credit to the testimony of Gervas, the monk of Canterbury, who flourished at the beginning of the thirteenth century, organs were introduced more than one hundred years before his time. Bede, who died in 735, says nothing of the use of organs, or other musical instruments, in our churches or convents, though he minutely describes the manner in which the psalms and hymns were sung; yet Mabillon and Muratori inform us, that organs, during the 10th century, became common in Italy and Germany, as well as in England; and that about the same time they had admission into the convents throughout Europe.

The church-organ consists of two parts; the main body, called the great organ, and the positive or little organ, which forms a small case or buffet, commonly placed before the great organ. The size of an organ is generally expressed by the length of its largest pipe; thus they say, an organ of 8, 16, 32 feet, &c. The organ in the cathedral church at Ulm in Germany is 93 feet high and 28 broad; its largest pipe is 13 inches diameter, and it has 16 pair of bellows.

Plate Organ, represents a barrel-organ made by Mr. Lincoln, Holborn, A, figs. 2 and 6, is the handle by which it is played; on its spindle is a crank *a*, that works the bellows which supply the organ with air: these bellows are in two distinct parts BD; and as the lower boards move round *f* as a centre, one of the sides is always filling with air by a valve in its under side, while the other is forcing its way through a valve in the board E into the regulator F, the moveable or upper board of which is pressed down by two wire springs *bb*. When the handle A is turned, the crank *a* by the rod *d*, moves the lower boards BD of the bellows up and down, so that they force the air alternately through their respective valves into the regulator: when a great quantity of air is forced into the regulator, it overcomes the springs, and raises the upper board; and during the time that the bellows supply no air, which is when the valves in the boards BD are shutting, the springs *bb* force down the board of the regulator, and drive the air out of it for the supply of the organ, till the bellows begin to act. The board E has a hole cut through it, which communicates with a passage *ee*, fig. 2; which conveys the air from the regulator to a trunk *g*, called the wind-chest, and which extends the whole length of the organ under the pipes G and H: the board which forms the top of this has a hole through it under every pipe, and is covered by a valve as *h*. *i* is a small wire, the end of which rests upon the valve, so as to open it when the wire is pushed down the passage; for the air is conveyed through the upper board of the wind-chest, under two sliders *kl*, called stops, which have handles (shewn in fig. 6.) coming through the frame, by which they can be moved in or out: these stops slide in tubes, lined with leather, which they fit very exactly, so as to prevent any air getting through by the sides of them; and the stops have as many holes cut through them as there are valves and pipes, and at the same distance from one another; so that when the stops are pushed in, the holes in them coincide with the passage from the valves to the pipes GH, so as to give the air free vent; and when they are drawn out, the spaces between the holes in the stops are brought over the passages, so as to close them, and prevent any air getting through. From the stop *k* the air is conveyed by a crooked passage to the wooden pipes H, and the slider *l* is to intercept the air for the metal pipes G. A section of each kind of pipe is shewn in figs. 3 and 4: *aa* fig. 3 is a cylindric pipe, usually of lead; to one end of this is soldered a conical pipe *bb* of the same metal, at the end *d* of which the air is admitted. Near the junction of the two pipes a piece of metal *e* is soldered, which fills up all the pipe, except a small cavity on one side, which is cut straight; and the edge of the conical pipe *bb* is bent straight, so as to leave a small crack, through which the air issues. The edge *n* of the cylindric pipe is cut to a sharp edge, and bent down to the line with the opening through which the air comes: when the air is blown through the end *d*, it rushes through the opening between the piece *e* and the edge of the pipe *bb*, the sound is formed by the edge *n* dividing the current of air, and the vibration of the air in the remainder of the tube *aa*: in large pipes a small piece of metal *o*, called the ear, is soldered on, which adds much to the sound. The wooden pipe, fig. 4, is composed of a square trunk of wood *aa*: in one end a block of wood *b* is glued; a small wooden pipe *d* is inserted into the lower end of this block to bring the air to the pipe, the end of which is partly closed by a plug of wood to adjust the quantity of air; in the leaden pipes this is done by pinching them up at the end. On one side of the block *b* a piece of oak is glued, between the edge of which and the block *b* the air issues, and is divided, as in the metal pipes, by the edge of one of the boards of the trunk, which is cut sharp for the purpose: the ends of the wooden pipes are closed by a plug of wood *h*, which is slid farther in or out, to adjust the pipe to the proper note. The spindle of the handle A, fig. 6, has an endless screw *m* upon it, which works into a wheel L, the barrel K (shewn separately in fig. 1.). This barrel is made of wood, and has pins drove into it, which pins, as it is turned round, lift up the keys *h*, fig. 6. shewn in fig. 5, where A is the barrel, the pins of which, as it turns, take hold of the end *e* of the keys *n*, and lift them up: these keys are supported by a bar B called the key-frame, on each side of which a brass plate *bb* is screwed, which has notches cut in it to guide each key: a wire *d* is put through each key, round which it moves as a centre; the end *f* of the key has a piece of mahogany fastened to it, to which is jointed the rod I, by a piece of leather. The lower end of this rod is jointed to the wire *i*, fig. 2, by which the valve *h* is opened as before described:- the spring under this valve throws the rod I upwards; and to prevent the end *e* of the key from touching the barrel, a screw *p* is put through the key-frame, the bottom of which is covered with leather, to catch the key without making any noise. The operation of the machine is as follows: When the handle A, fig. 6, is turned, it works the bellows by the crank *a*, and forces the air to the wind chest *g*, fig. 2; at the same time the screw *m* turns the barrel K, fig. 6, slowly round: the pins in its surface lift up the end *e*, fig. 5, of the key, which depresses the other end, and by the rods I and wire *i*, fig. 2, opens the valve, and allows the air (if the stops *k* or *l* are open) to enter the pipe of the proper note, and sound it. As the barrel turns, that key is dropped, and the spring shuts the valve; another pipe, corresponding to the next note of the tune, is then opened and so on till the tune is completed. If the tune is wanted to be played in a high key, the stop *l* is drawn out, and the metal pipes are used; if in a low key the wooden pipes, which are an octave lower, are played, by pulling out the stop K and pushing in the other; if the tune is to be played very loud, both are drawn out; and when both are pushed in, no sound is produced. As a different quantity of air is wanted for playing the metal and wooden pipes, the bellows are made large enough to supply both at once; and when only one is used, the air escapes through a valve in the upper board of the regulator F: this valve has a long handle, and is kept shut by a wire spring; when the board of the regulator is raised to a certain height, the handle of the valve *m* meets a part of the frame, the valve is opened, and the air escapes. The frame in which the barrel is mounted, fig. 1. is slid into a groove M, figs. 2 and 6: to one of the uprights of the frame, a piece of brass N, fig. 1, is screwed; this projects through the outside board of the organ, as shewn in fig. 7, and has as many notches cut in it as the barrel plays different tunes; a bolt O slides into any of these notches, so as to keep the piece N in any place where it is set over the end of this bolt; another bolt P slides so that P must be withdrawn before O can be moved. The bolt P has a wire *w*, figs. 2, 5, and 6, projecting from the back of it through the board: this wire acts upon one end of the lever *r*, so as to push it down when the bolt is drawn back. The key-frame E, fig. 5, is not fastened down to the frame of the organ, but has two pieces of iron plate *g* fastened to the ends of it: the other end of this moves round a screw, as a centre, so that the frame and keys can be turned up clear of the barrel; it has a wire spring S, to keep it down, and a screw *t* regulates its distance from the barrel when down. One end of the lever *r* is put under the key-frame, so that when the outer end is pushed down by drawing back the bolt P, fig. 7, the other will raise the key-frame: the bolt O is then at liberty to be drawn back; and the piece N can be set, and fixed at another notch, which causes the organ to play another tune, by moving the barrel along a small distance, which brings a fresh set of pins under the keys, which are differently disposed. By the arrangement of the bolts as above, the barrel can never be moved without first fitting up the keys, so that there is no danger of breaking the keys of pins in the barrel.

The pannels of the organ are slid into grooves cut in the four uprights of the frame.

ORIBASIA, a genus of the monogynia order, in the pentandria class of plants, and in the natural method ranking under the forty-seventh order, stellatæ. The corolla is small, tubulated, and monopetalous. The pericarpium is a globular berry, grooved longitudinally; is quinquelocular, and contains one seed. Of this there are six species, all natives of the warmer parts of America, viz. 1. Officinalis: the natives of Guiana make infusions of the leaves, and give them in cases of spasmodic asthma. 2. Racemosa. 3. Violacea. 4. Lutea. 5. Paniculata. 6. Longiflora.

ORICHALCUM. See Zinc.

ORIGANUM, *origany*, or *marjoram*, a genus of the gymnospermia order, in the didynamia class of plants, and in the natural method ranking under the forty-second order, verticillatæ. There is a strobilus or cone collecting the calcyes together. The principal species are, two hardy perennials and an annual for the open ground, and five perennials for the greenhouse: viz. 1. The vulgare, or wild pot-marjoram. 2. The heracleoticum, or winter sweet-marjoram. These are finely-scented aromatics, excellent for culinary purposes, particularly for broths, soups, &c. they have likewise merit for medical uses, and for giving fragrance to ointments; so that the plants are proper both for kitchen and physic gardens, and may also be employed in the pleasure-ground as plants of variety. 3. The marjorana, or annual sweet-marjoram, is an aromatic of the highest fragrance, is admirable for kitchen use, and excellent for nosegays. It is often called knotted marjoram, from the flowers growing in close knotted-like heads. The following mostly assume an undershrubby growth; frequently with abiding stalks, if they shelter here in winter: 4. The dictamnus or dittany of Crete. 5. The sipyleum, or origanum of mount Sipylus. 6. The creticum, or Cretan origany. 7. The smyrnæum, or Smyrna origany. 8. The ægyptiacum, or Egyptian origany. There are four other species.

ORIGENISTS, in church-history, a Christian sect in the fourth century, so called from their drawing their opinions from the writings of Origen. The origenists maintained, that the souls of men had a pre-existent state, that they were holy intelligences, and had sinned in heaven before the body was created: that Christ is only the son of God by adoption.

ORIGINAL, in the court of king's bench, the usual original writ issued in the actions, as for action of trespass upon the case. And this court does not issue originals in actions of debt, covenant, or account, &c. whereas the court of common-pleas proceeds by original in all kinds of actions; but to arrest and sue a party to outlawry, it is used in both cases. See Impey's B. R. and C. B.

ORIOLUS, *oriole*, in ornithology, a genus belonging to the order of picæ. The bill in this genus is straight, conic, very sharp-pointed; edges cultrated, inclining inwards; mandibles of equal length. Nostrils small, placed at the base of the bill, and partly covered. Tongue divided at the end. Toes, three forward, one backward; the middle joined near the base to the outmost one. These birds are inhabitants of America, except in a few instances; they are a noisy, gregarious, frugivorous, granivorous, and voracious race, very numerous, and often have pensile nests. The several species, which are very numerous, since Mr. Latham describes no less than forty-five, seem to be principally distinguished by their colour.

1. The first species, is called the oriolus Baltimore, by Linnæus, and the Baltimore oriole by Pennant, and is an inhabitant of North America, which country it quits before winter, and probably retires to Mexico; the xochitotl of Fernandez seeming to be of the same species. The head, throat, neck, and upper part of the back of the male, are described to be black; the lesser coverts of the wings orange; the greater black, tipt with white; the breast, belly, lower part of the back, and coverts of the tail, of a bright orange. The head and back of the female are orange, edged with pale brown; the tail dusky, edged with yellow. The length both of the male and female is seven inches. This bird suspends its nest to the horizontal forks of the tulip and poplar trees, formed of the filaments of some tough plants, curiously woven, mixed with wool, and lined with hairs. It is of a pear-shape, open at top, with a hole on the side through which the young are fed. In some parts of North America, this species, from its brilliant colour, is called the fiery hang-nest. It is named the Baltimore bird, from its colours resembling those in the arms of the late lord Baltimore, whose family were proprietors of Maryland.

2. The sharp-tailed oriole is about the size of a lark; the bill is dusky; the crown is brown and cinereous; the cheeks are brown, bounded above and below with deep dull yellow. The throat is white; the breast, sides, thighs, and vent, are a dull pale yellow, spotted with brown; the belly is white; the back is varied with ash-colour, black, and white; the wing-coverts are dusky, with ferruginous edges.

The other species of the oriole, (see Plate Nat. Hist. figs. 301 and 302.) according to Mr. Pennant's enumeration, are the white-backed, the bastard, the black, the brown-headed, the rusty, the white-headed, the Hudsonian white-headed, the olive, the yellow-throated, the unalaschka, the sharp-tailed, and the red-wing. This last species is known in America by the name of the red-winged starling and the swamp blackbird. Although they appear at New York only from April to October, they probably continue through the whole year in the southern parts; at least, Catesby and Latham make no mention of their departure. They are seen at times in such prodigious flocks, as even to obscure the sky. They were esteemed the pest of the colonies, making most dreadful havock among the maize and other grain, both when newly-sown and ripe. They are very bold, and not to be terrified by a gun; for, notwithstanding the sportsman makes slaughter in a flock, the remainder will take a short flight, and settle again in the same field. The farmers sometimes attempt their destruction, by steeping the maize before they sow it in a decoction of white hellebore. The birds that eat this prepared corn, are seized with a vertigo, and fall down, which sometimes drives the rest away. This potion is particularly aimed at the purple grackles or purple jackdaw, which consorts in myriads with this species, as if in conspiracy against the labours of the husbandman. The fowler seldom fires among the flocks without killing some of each. They appear in the greatest numbers in autumn, when they receive additions from the retired parts of the country, to prey on the ripened maize. Some of the colonies established a reward of three-pence a dozen for the extirpation of the jackdaws; and in New England, the intent was almost effected at the cost of the inhabitants; who discovered, at length, that Providence had not formed these seemingly destructive birds in vain. Notwithstanding they caused such havock among the grain, they made ample recompence, by clearing the ground of the noxious worms, the caterpillar of the bruchus pisi, or peas-beetle, in particular, with which it abounds. As soon as the birds were destroyed, the reptiles had full leave to multiply; and the consequence was the total loss of the grass in 1749, when the New Englanders, repenting too late, were obliged to get their hay from Pennsylvania, and even from Great Britain.

ORION, in astronomy, a constellation of the southern hemisphere. See Astronomy.

Orion's ring, in astronomy, a constellation more usually called Eridanus. See Eridanus.

ORNITHOGALUM, *star of Bethlehem*, a genus of the hexandria monogynia class of plants, the corolla whereof consists of six petals, of a lanceolated figure from the base to the middle, erect from thence to the points, plano-patent; they are permanent, but lose their colour: the fruit is a round angulated capsule, formed of three valves, and containing three cells; the seeds are numerous and roundish, the receptacle columnar.

There are thirty-five species, all of them herbaceous and perennial, rising from three to six feet high, having stalks terminated with long spikes of hexapetalous, star-shaped, white and yellow flowers. Six of the species are very hardy, and will prosper in any situation: but one, namely the capense, a native of the Cape of Good Hope, requires the assistance of artificial warmth to preserve it in this country.

ORNITHOLOGY, that branch of zoology, which treats of birds. See Bird. Linnæus, whose ornithology we have followed, arranges the whole class of birds under six orders, according to the different figures of their beaks, viz.

1. Accipitres, upper mandible with an an-

gular projection. 2. Picæ, bill compressed convex; with feet formed for perching or climbing. 3. Anseres, bill covered with skin, broad at the tip; some with and some without teeth. 4. Grallæ, bill roundish, tongue fleshy; some with three some with four toes. 5. Gallinæ, bill convex, upper mandible arched. 6. Passeres, bill conic, sharp-pointed.

ORNITHOPUS, *bird's foot*, a genus of the diadelphia decandria class of plants, with a papilionaceous flower: its fruit is an oblong jointed pod, of a cylindrical figure, and containing in each joint a single roundish seed; add to this, that several of these pods usually grow together. There are five species.

The leaves of this plant are said to be good for a hernia, and for breaking and expelling the stone of the kidneys or bladder.

ORNITHORHYNCHUS PARADOXUS, from New South Wales, a singular quadruped, which has not yet been properly classed in the Linnæan system. The most remarkable circumstance in this curious animal, is the great similarity of its head with that of a duck, which, however, is still more striking in its internal structure. From the external form of the scull of this animal, one might be more easily led to conclude that it belonged to such an aquatic bird, than to a creature of the mammalia tribe. Both the jaws are as broad and low as in a duck, and the calvaria has no traces of a suture, as is generally the case in full-grown birds. There is likewise a singularity in the cavity of the scull, of which nothing like it is known in any quadruped animal of the mammalia, though there exists something analogous in the class of birds, namely, a considerable bony falx, which is situated along the middle of the os frontis, and the ossa bregmatis. This processus is in general scarcely to be seen in the mammalia, even in those that have a bony tentorium cerebelli. The mandible of this animal is very singular, consisting of a beak, the under part of which has its margin indented as in ducks, and of the proper instrument for chewing that is situated behind, within the cheeks. This has no teeth, nor even the traces of alveoli, but only two broad processes of a peculiar formation on each side, whose undulated superficies fit one another. Dr. Shaw says of the specimen he examined, that it had no teeth, "dentium nulla sunt vestigia." But sir Joseph Banks informs us, that Mr. Home has found, in a specimen that belongs to the Society of Natural History at Newcastle, on each side of the jaws, two small and flat molar teeth. The fore part of this anomalous mandible, or the beak, is covered and bordered with a coriaceous skin, in which three parts are to be distinguished: 1. The proper integument of the beak (integumentum rostri). 2. The labiated margins of it (margines labiales). 3. A curious edge of the skin of the beak (limbus transversarius). Into these three parts of that membrane numerous nerves are distributed, of which those in the upper part of the beak arise from the second branch of the fifth pair, viz. in the limbus transversarius; that which penetrates through the foramen infraorbitale, in the margo labialis; that which comes forth behind the ossa intermaxillaria, and to the integumentum rostri, three branches, which run out between the ossa intermaxillaria. From this quantity of nerves, with which the integument of the beak is provided, no doubt is left of this part being intended as the organ of feeling, a sense which, besides men and the quadrumanes, very few mammalia enjoy, that is to say, few animals possess the faculty of distinguishing the form of external objects and their qualities by organs destined for that purpose; a property that is different from the common feeling, by which every animal is able to perceive the temperature and presence of sensible objects, but without being informed by the touch of them, of their peculiar qualities. Thus, for instance, the skin in the wings of a bat, and its ear, serve probably as organs of common feeling, by means of which they are enabled to flutter, after being blinded, without flying against any thing. The whiskers (vibrissæ) of many animals seem likewise to serve for the purpose of informing them of the presence of sensible bodies, on which account Dr. Darwin compares them with the antennæ of insects; but they are not able to inform themselves of the properties of those objects. It is true that the snout of a mole has been considered by Derham, and the snout and tongue of many other animals likewise by Buffon, as organs of touching; but this seems only to be their secondary use. The same may be said of the elephant's trunk, which Buffon also conceives to be an organ of touching, although from its manner of living, the necessity of such an organ of touching does not appear. The ornithorhynchus, however, is an animal which, from the similarity of its abode, and the manner of searching for food, agrees much with the duck, on which account it has been equally provided by nature with an organ for touching, viz. with the integument of the beak, richly endowed with nerves. This instance of analogy in the structure of a singular organ of sense in two species of animals from classes quite different, is highly instructive for comparative physiology, and on this account the ornithorhynchus belongs to one of the most remarkable phenomena of zoology, and may in general be looked upon as one of the most interesting discoveries with which that part of natural history has been enriched during the last century. See Plate Nat. Hist. fig. 303.

OROBANCHE, *broom-rape*, a genus of the didynamia angiospermia class of plants, ranking under the 40th order, personatæ. The corolla is monopetalous and ringent; and its fruit an oblong capsule formed of two valves, and containing a great many minute seeds; the calyx is bifid. There is a glandule under the base of the germen. There are fourteen species.

OROBUS, *bitter vetch*, a genus of the decandria order, in the diadelphia class of plants; and in the natural method ranking under the 32d order, papilionaceæ. The style is linear; the calyx obtuse at the base, with the upper segments deeper and shorter than the rest. There are 16 species. All of them have fibrated roots, which are perennial, but are annual in stalk, rising early in spring and decaying in autumn. They are very hardy plants, and prosper in any common soil of a garden. Most of the sorts are very floriferous, and the flowers conspicuous and ornamental for adorning the flower-compartments. The Scotch Highlanders have a great esteem for the tubercles of the roots of the tuberosus, or species sometimes called wood-pea. They dry and chew them in general to give a better relish to their liquor; they also affirm that they are good against most disorders of the breast, and that by the use of them they are enabled to resist hunger and thirst for a long time. In Breadalbane and Ross-shire, they sometimes bruise and steep them in water, and make an agreeable fermented liquor with them. They have a sweet taste, something like the roots of liquorice; and, when boiled, we are told, they are nutritious and well flavoured; and in times of scarcity have served as a substitute for bread.

ORONTIUM, a genus of the monogynia order, in the hexandria class of plants; and in the natural method ranking under the second order, piperitæ. The spadix is cylindrical, covered with florets; the corolla hexapetalous and naked; there is no style; the follicles are monospermous. There are two species, marsh plants of Canada and Japan.

ORPHAN: in the city of London there is a court of record established for the care and government of orphans.

ORPIMENT. See Arsenic.

ORRERY, a curious machine for representing the motions and appearances of the heavenly bodies. We shall in this place merely shew the theory of the wheels, leaving a more particular description for the article Planetarium. We must first compare and find out the proportion which the periodical times, or revolutions, of the primary planets, bear to that of the earth; and they are such as are expressed in the table below: where the first column is the time of the earth's period in days and decimal parts; the second, that of the planets; the third and fourth are numbers in the same proportion to each other: as

365,25 : 88	☿	:: 83 : 20,	for Merc.
365,25 : 224,7	♀	:: 52 : 32,	for Venus.
365,25 : 686,9	♂	:: 40 : 75,	for Mars.
365,25 : 4332,5	♃	:: 7 : 83,	for Jupiter.
365,25 : 10759,3	♄	:: 5 : 148,	for Saturn.

If we now suppose a spindle or arbor with six wheels fixed upon it in an horizontal position, having the number of teeth in each corresponding to the numbers in the third column, viz. the wheel AM (see Plate Observatory, fig. 6.) of 83 teeth, BL of 52, CK of 50 (for the earth), DI of 40, EH of 7, and FG of 5; and another set of wheels moving freely about an arbor, having the number of teeth in the fourth column, viz. AN of 20, BO of 32, CP of 50 (for the earth), DQ of 75, ER of 83, and FS of 148; then, if those two arbors of fixed and moveable wheels are made of the size, and fixed at the distance from each other, as here represented in the scheme, the teeth of the former will take those of the latter, and turn them very freely, when the machine is in motion.

These arbors, with their wheels, are to be placed in a box of an adequate size, in a perpendicular position: the arbor of fixed wheels to move in pivots at the top and bottom of the box; and the arbor of moveable wheels to move in pivots at the top and bottom of the box; and the arbor of moveable wheels to go through the top of the box, on a proper height, on the top of which is to be placed a round ball, gilt with gold, to represent the sun. On each of the moveable wheels is to be fixed a socket, or tube, ascending above the top of the box, and having on the top a wire fixed, and bent at a proper distance into a right angle upwards, bearing on the top a small round ball, representing its proper planet.

If then on the lower part of the arbor of fixed wheels is placed a pinion of screw-teeth, a winch turning a spindle with an endless screw, playing in the teeth of the arbor, will turn it with all its wheels; and these wheels will move the others about with their planets, in their proper and respective periods of time, very exactly. For, while the fixed wheel CK moves its equal CP once round, the wheel AM will move AN a little more than four times round, and so will nicely exhibit the motion of Mercury; and the wheel FG will turn the wheel FS about $\frac{1}{29,5}$ round, and so will truly represent the motion of Saturn, and the same is to be observed of all the rest.

ORTEGIA, a genus of the class and order triandria monogynia. The calyx is five-leaved; corolla none; capsule one-celled; seeds many. There are two species, trailing plants of Spain and Italy.

ORTHOGRAPHY, that part of grammar which teaches the nature and affections of letters, and the just method of spelling or writing.

ORTHOGRAPHY, in geometry, the art of drawing or delineating the fore-right plan of any object, and of expressing the heights or elevations of each part. It is called orthography, from its determining things by perpendicular lines falling on the geometrical plane.

ORTHOGRAPHY, in architecture, the elevation of a building.

ORTHOGRAPHY. See PERSPECTIVE.

ORTOLAN. See EMBERIZA.

ORYZA, *rice*, a genus of the digynia order, in the hexandria class of plants; and in the natural method ranking under the 4th order, gramina. The calyx is a bivalved uniflorous glume; the corolla bivalved, nearly equal, and adhering to the seed. There is but one species, namely, the sativa or common rice. This plant is greatly cultivated in most of the Eastern countries, where it is the chief support of the inhabitants; and great quantities of it are brought into England and other European countries every year, where it is much esteemed for puddings, &c. it being too tender to be produced in these northern countries without the assistance of artificial heat; but from some seeds which were formerly sent to Carolina there have been great quantities produced, and it is found to succeed there as well as in the Eastern countries.

This plant grows upon moist soils, where the ground can be flowed over with water after it is come up.

Rice is the chief commodity and riches of Damieta in Egypt, and Dr. Hasselquist gives the following description of the manner in which they dress and separate it from the husks. "It is pounded by hollow iron pestles of a cylindrical form, lifted up by a wheel worked by oxen. A person sitting between the two pestles, pushes forward the rice when the pestles are rising; another sifts, winnows, and lays it under the pestles. In this manner they continue working it until it is entirely free from chaff and husks. When clean, they add a thirtieth part of salt, and pound them together; by which the rice, formerly grey, becomes white. After this purification, it is passed through a fine sieve to part the salt from the rice; and then it is ready for sale." Damieta sells every year 60,800 sacks of rice, the greatest part of which goes to Turkey, some to Leghorn, Marseilles, and Venice.

Rice, according to Dr. Cullen, is preferable to all other kinds of grain, both for largeness of produce, quantity of nourishment, and goodness. This, he says, is plain from macerating the different grains in water; for, as the rice swells to the largest size, so its parts are more intimately divided. Rice is said to affect the eyes; but this is purely prejudice. Thus it is alleged a particular people of Asia, who live on this grain, are blind-eyed; but if the soil is sandy, and not much covered with herbage, and the people are much employed in the field, this affection of their eyes may be owing to the strong reflection of the rays of light from this sandy soil; and our author is the more inclined to this opinion, because no such effect is observed in Carolina, where rice is commonly used.

OSBECKIA, a genus of the octandria monogynia class and order. The cal. is four-cleft; cor. four and five-petalled; stam. eight or ten; anthers beaked; caps. inferior, four-celled. There is one species, a trifling plant of China.

OSCILLATION, in mechanics, the vibration, or reciprocal ascent and descent, of a pendulum. See PENDULUM.

It is demonstrated, that the time of a complete oscillation in a cycloid, is to the time in which a body would fall through the axis of that cycloid, as the circumference of a circle to its diameter; whence it follows, 1. That the oscillations in the cycloid are all performed in equal times, as being all in the same ratio to the time in which a body falls through the diameter of the generating circle. 2. As the middle part of the cycloid may be conceived to coincide with the generating circle, the time in a small arch of that circle will be nearly equal to the time in the cycloid; and hence the reason is evident, why the times in very little arches are equal. 3. The time of a complete oscillation in any little arch of a circle, is to the time in which a body would fall through half the radius, as the circumference of a circle, to its diameter; and since the latter time is half the time in which a body would fall through the whole diameter, or any chord, it follows that the time of an oscillation in any little arch, is to the time in which a body would fall through its chord, as the semicircle to the diameter. 4. The times of the oscillations in cycloids, or in small arches of circles, are in a sub-duplicate ratio of the lengths of the pendulums. 5. But if the bodies that oscillate are acted on by unequal accelerating forces, then the oscillation will be performed in times that are to one another in the ratio compounded of the direct subduplicate ratio of the lengths of the pendulums, and inverse subduplicate ratio of the accelerating forces. Hence it appears that if oscillations of unequal pendulums are performed in the same time, the accelerating gravities of these pendulums must be as their lengths; and thus we conclude, that the force of gravity decreases as you go towards the equator, since we find that the lengths of pendulums that vibrate seconds are always less at a less distance from the equator. 6. The space described by a falling body in any given time, may be exactly known; for finding, by experiments, what pendulum oscillates in that time, the half of the pendulum will be to the space required, in the duplicate ratio of the diameter of a circle to the circumference.

Centre of OSCILLATION. See CENTRE.

OSMITES, a genus of the class and order syngenesia polygamia frustranea. The cal. is imbricate, scariose; cor. of the ray ligulate; down obsolete; recept. chaffy. There are four species, shrubs of the Cape.

OSMUNDA, *moon-wort*; a genus of the order of filices, in the cryptogamia class of plants. There are twenty-seven species; the most remarkable of which is the regalis, osmund-royal, or flowering fern. This is a native of Britain, growing in putrid marshes. Its leaf is doubly winged, bearing bunches of flowers at the ends. The root boiled in water is very slimy; and is used in the north to stiffen linen instead of starch. Some of the leaves only bear flowers.

OSSIFICATION, the formation of bones. See CONCRETIONS.

OSTEOLOGY. See ANATOMY.

OSTEOSPERMUM, a genus of the class and order syngenesia polygamia necessaria. The cal. is simple, in two rows, many-leaved, almost equal; seeds globular, coloured, bony; down none; recept. naked. There are 17 species, shrubs of the Cape.

OSTRACION, in ichthyology, a genus of the branchiostegous order of fishes, of a globose, oval, or ovato-quadrangular figure: the skin is always very firm and hard; and is in some species smooth, in others entirely covered with spines; and, finally, in some the spines entirely occupy only particular places; there are no belly-fins, and the others are five in number, viz. two pectoral or lateral fins, one on the back, the pinna ani, and the tail. There are 12 species of this genus: the triqueter has a triangular body unarmed; inhabits India; the back appearing as if covered with rhombic marks cut transversely. The quadricornis, with frontal and subcaudal spines, inhabits India and Guinea.

OSTRACION, trunk-fish, a genus of fishes, of the order nantes; the generic character is, teeth pointing forwards, cylindric, rather blunt; body mailed by a bony covering.

1. Ostracion triqueter, triquetral trunk-fish; the ostracions or trunk-fishes are so strikingly distinguished by their bony crust or covering, that no difficulty can arise to the ichthyological student in referring them to their proper genus. The investigation of the species however demands a greater degree of attention, and such is the similarity between some of these, that it remains doubt-

ful whether they should be considered as truly distinct, or as constituting mere sexual differences.

The triquetral trunk-fish measures about twelve inches in length, and is, as its name imports, of a trigonal shape, the sides sloping obliquely from the ridge of the back, and the abdomen being flat; the whole animal, except to within a small distance from the tail, is completely enveloped in a bony covering, divided into well-defined hexagonal spaces, and covered (as in the whole genus) with a transparent epidermis like that of the armadillo among quadrupeds; the usual colour is a subferruginous brown, with a white spot in the centre of each hexagon, which is also marked by fine rays diverging from the centre to the edges: the fins are yellowish, and the tail rounded; the naked part of the extremity of the body or base of the tail being marked with white specks, similar to those on the crustaceous part of the animal: the pectoral fins are rather small than large, and of a rounded shape: the dorsal and anal are also rather small, and are situated opposite each other towards the extremity of the body, and, like the rest of the genus, this fish is destitute of ventral fins. It is a native of the Indian and American seas, and is supposed to feed on the smaller crustacea, shell-fish, and sea-worms. It is said to be considered as an excellent fish for the table, and is held in high estimation among the East Indians. There are ten species.

2. Ostracion quadricornis, four-horned trunk-fish; length twelve inches; shape subtrigonal; the back, when viewed in profile, strongly arched, and having a smooth outline; mail divided into large hexagons marked with numerous and very small tubercles; on the top of the head two very strong spines pointing forwards; and from the hind part of the abdomen, immediately before the anal fin, two more spines pointing backwards; colour of the mailed part subviolaceous brown, with darker streaks irregularly dispersed over the whole; naked part of the body near the tail, yellowish-brown, marked with deep-brown spots; fins and tail yellowish-brown. Native of the Indian and American seas. See Plate Nat. Hist. fig. 304.

OSTREA, the *oyster*, in zoology, a genus belonging to the order of vermes testacea. The shell has two unequal valves; the cardo has no teeth, but a small hollowed one with transverse lateral streaks. There are thirty-one species, principally distinguished by peculiarities in their shells. The common oyster is reckoned an excellent food; and is eaten both raw and variously prepared. The character of the genus, in the words of Barbut, is, "The animal a tethys; the shell bivalve, unequivalve, with something like ears; the hinge void of teeth, with a deep oval hole, and transverse streaks on the sides. There is no womb nor anus." The genus is divided into four families, of which ostrea is the last.

The oyster differs from the muscle in being utterly unable to change its situation. It is entirely without a tongue which answers the purposes of an arm in the other animal, but nevertheless is often attached very firmly to any object it happens to approach. Nothing is so common in the rivers of the tropical climates, as to see oysters growing even amidst the branches of the forest. Many trees, which grow along the banks of the stream, often bend their branches into the water, and particularly the mangrove, which chiefly delights in a moist situation. To these the oysters hang in clusters, like apples upon the most fertile trees; and in proportion as the weight of the fish sinks the plant into the water, where it still continues growing, the number of oysters encrease, and hang upon the branches. This is effected by means of a glue proper to themselves, which when it cements, the joining is as hard as the shell, and is as difficultly broken.

Oysters usually cast their spawn in May, which at first appears like drops of candle-grease, and sticks to any hard substance it falls upon. These are covered with a shell in two or three days; and in three years the animal is large enough to be brought to market. As they invariably remain in the places where they are laid, and as they grow without any other seeming food than the afflux of sea-water, it is the custom at Colchester, and other parts of England, where the tide settles in marshes on land, to pick up great quantities of small oysters along the shore, which, when first gathered, seldom exceed the size of sixpence. These are deposited in beds where the tide comes in, and in two or three years grow to a tolerable size. They are said to be better tasted for being thus sheltered from the agitations of the deep; and a mixture of fresh water entering into these repositories, is said to improve their flavour, and increase their growth and fatness.

The oysters, however, which are prepared in this manner, are by no means so large as those found sticking to rocks at the bottom of the sea, usually called rock-oysters. These are sometimes found as broad as a plate, and are admired by some as excellent food. But what is the size of these compared to the oysters of the East Indies, some of whose shells have been seen two feet over! The oysters found along the coast of Coromandel, are capable of furnishing a plentiful meal for eight or ten men; but it seems universally agreed that they are no way comparable to ours for delicacy of flavour.

OSTRICH. See STRUTHIO.

OSYRIS, *poet's rosemary*, a genus of the diœcia triandria class of plants, without any flower-petals; the fruit is a globose unilocular berry, containing a single osseous seed. There are two species. This whole shrub is astringent, and consequently good in fluxes.

OTHERA, a genus of the tetrandria monogynia class and order. The cal. is four-parted; pet. four; stigma sessile; caps. There is one species, a shrub of Japan.

OTHONNA, a genus of the polygamia necessaria order, in the syngenesia class of plants; and in the natural method ranking under the 49th order, compositæ. The receptacle is naked; there is almost no pappus; the calyx is monophyllous, multifid, and nearly cylindrical. There are 27 species.

OTIS, the **bustard**, in ornithology, a distinct genus of birds, of the order of the gallinæ, the characters of which are these: there are three toes on each foot, all turned forwards; and the head is naked, or has no comb. There are four species, principally distinguished by their colour. One of the species, the tarda, or bustard (see Plate Nat. Hist. fig. 305.), is the largest of the British land fowl, the male at a medium weighing 25 pounds; there are instances of some very old ones weighing 27: the breadth nine feet; the length near four. Besides the size and difference of colour, the male is distinguished from the female by a tuft of feathers about five inches long on each side of the lower mandible. Its neck and head are ash-coloured; the back is barred transversely with black, and bright rust-colour; the greater quill-feathers are black; the belly white; the tail is marked with broad red and black bars, and consists of twenty feathers; the legs dusky.

The female is about half the size of the male: the crown of the head is of a deep orange, traversed with black lines; the rest of the head is brown. The lower part of the fore-side of the neck is ash-coloured; in other respects it resembles the male, only the colours of the back and wings are more dull.

The birds inhabit most of the open countries of the south and east parts of this island, from Dorsetshire as far as the Wolds in Yorkshire. They are exceedingly shy, and difficult to be shot; run very fast; and when on the wing can fly, though slowly, many miles without resting. It is said, that they take flight with difficulty, and are sometimes run down with greyhounds. They keep near their old haunts, seldom wandering above twenty or thirty miles. Their food is corn and other vegetables, and those large earth-worms that appear in great quantities on the downs before sun-rising in the summer. These are replete with moisture, answer the purpose of liquids, and enable them to live long without drinking on those extensive and dry tracts. Besides this, nature has given the males an admirable magazine for their security against drought, being a pouch whose entrance lies immediately under the tongue, and which is capable of holding near seven quarts; and this they probably fill with water, to supply the hen when sitting, or the young before they can fly. Bustards lay only two eggs of the size of those of a goose, of a pale olive-brown, marked with spots of a dark colour; they make no nest, only scrape a hole in the ground. In autumn they are (in Wiltshire) generally found in large turnip-fields near the downs, and in flocks of 50 or more.

OTTER. See MUSTELA.

OVAL, an oblong curvilinear figure, otherwise called ellipsis. The proper oval, however, or egg-shape, differs considerably from that of the ellipsis, being an irregular figure, narrower at one end than at the other; whereas the ellipsis, or mathematical oval, is equally broad at each end; though it must be owned, these two are commonly confounded together, even geometricians calling the oval a false ellipsis.

OVARIES. See ANATOMY, and COMPARATIVE ANATOMY.

OVIEDA, a genus of the didynamia angiospermia class and order. The cal. is five-cleft; cor. tube subylindric, superior, very long; berry globular. There are two species, shrubs of South America.

OVER-HALE, in the sea language. A rope is said to be overhaled when drawn too stiff, or haled the contrary way.

OVER-RAKE, among seamen: when a ship riding at anchor, so overbeats herself into a head-sea, that she is washed by the waves breaking in upon her, they say the waves over-rake her.

OVERSEERS *of the poor*. The proper number of overseers of the poor for each parish, must be duly appointed, and sworn before two justices of the peace, one whereof must be of the quorum.

The overseers thus appointed, and taking on them the office, shall within fourteen days, receive the books of assessments, and of accounts, from their predecessors, and what money and materials shall be in their hands, and reimburse them for their arrears. 17 Geo. II. c. 38.

And shall take order from time to time, with the consent of two such justices as aforesaid, for setting to work the children of such parents who shall not by the said overseers be thought able to keep or maintain them, and using no ordinary or daily trade of life to get their living by. 43 Eliz. c. 2.

By the 17 Geo. II. c. 38. if any person shall be aggrieved by any thing done or omitted by the churchwardens and overseers, or by any of his majesty's justices of the peace, he may, giving reasonable notice to the churchwardens or overseers, appeal to the next general or quarter-sessions, where the same shall be heard, or finally determined; but if reasonable notice is not given, then they shall adjourn the appeal to the next general or quarter-sessions; and the court may award reasonable costs to either party, as they may do by 8 and 9 W. in case of appeals concerning settlements. See POOR.

OVERT ACT. In the case of treason in compassing or imagining the death of the king, this imagining must be manifested by some open act; otherwise being only an act of the mind, it cannot fall under any judicial cognizance. Bare words are held not to amount to an overt act, unless put into writing, in which case they are then held to be an overt act, as arguing a more deliberate intention. No evidence shall be admitted of any overt act, that is not expressly laid in the indictment. 7 W. c. 3.

OVIS, *sheep*, a genus of quadrupeds of the order pecora: the generic character is, horns hollow, wrinkled, turning backwards, and spirally intorted; front-teeth, eight in the lower jaw; canine-teeth, none.

1. Ovis ammon, argali. As the capra ægagrus, or Caucasan ibex, is supposed to be the original of the domestic goat, so the ovis ammon, argali, or musimon, is believed to be the chief primæval stock from which all the kinds of domestic sheep have proceeded; many of which differ full as widely both from each other and their archetype as the goats.

Argali, or wild sheep, is an inhabitant of rocky or mountainous regions, and is chiefly found in the alpine parts of Asia. It was first observed by Dr. Pallas throughout the vast chain of mountains extending through the middle of the continent to the Eastern sea. In Kamtschatka it is plentiful; it occurs also in Barbary, in the mountains of Greece, and in the islands of Corsica and Sardinia; differing merely in a few slight particulars of colour and size, according to its climate.

The general size of the argali is that of a small fallow deer. Its colour is a greyish ferruginous brown above, and whitish beneath; the face is also whitish, and behind each shoulder is often observed a dusky spot or patch; the legs, at least in the European kind, are commonly white; the head strongly resembles that of a ram, but the ears are smaller in proportion, the neck more slender; the body large; the limbs slender but strong; the tail very short, being hardly more than three inches in length; the horns in the full-grown or old animals, are extremely large, placed on the top of the head, and stand close at their base, rising first upwards, and then bending down and twisting outwards as in the common ram; the body is covered with hair instead of wool, in which particular consists its chief difference from the general aspect of a sheep; but in winter the face, and particularly the part about the tip of the nose, becomes whiter, the back of a more ferruginous cast, and the hair, which in summer is close, like that of a deer, becomes somewhat rough, wavy, and a little curled, consisting of a kind of wool intermixed with hair, and concealing at its roots a fine white woolly down; the hair about the neck and shoulders, as well as under the throat, is considerably longer than on the other parts. The female is inferior in size to the male, and has smaller and less curved horns.

In Siberia the argali is chiefly seen on the tops of the highest mountains exposed to the sun, and free from woods. The animals generally go in small flocks; they produce their young in the middle of March, and have one, and sometimes two, at a birth. The young, when first born, are covered with a soft, grey, curling fleece, which gradually changes into hair towards the end of summer.

The horns of the old males grow to a vast size, and have been found of the length of two Russian yards, measured along the spires; weighing fifteen pounds each. We are assured by father Rubruquis, a traveller in the thirteenth century, that he had seen some of the horns so large that he could hardly lift a pair with one hand, and that the Tartars make great drinking-cups of them. A more modern traveller has asserted, that young foxes occasionally shelter themselves in such as are here and there found in the deserts.

In Corsica, the argali is known by the name of mufro; where it is so wild as rarely to be taken alive, but is shot by the hunters, who lie in wait for it among the mountains. When the young are taken, however, which is sometimes the case when the parent is shot, they are observed to be very readily tamed.

From the above description it will sufficiently appear, that the wild sheep is by no means that seemingly helpless animal which we view in a state of confinement in artificial life; but in the highest degree active and vigorous. It is supposed to live about fourteen years.

2. Ovis aries, the common sheep. This animal is so generally known, that a particular description of its form and manners becomes unnecessary. The domestic sheep, in its most valuable or woolly state, exists hardly any where in perfection except in Europe, and some of the temperate parts of Asia. When transported into very warm climates, it loses its peculiar covering, and appears coated with hair, having only a short wool next the skin. In very cold climates also, the exterior part of the wool is observed to be hard and coarse, though the interior is more soft and fine. In England, and some other European regions, the wool acquires a peculiar length and fineness, and is best adapted to the various purposes of commerce. That of Spain is still finer, but less proper for using alone; and is mixed with the English for the superior kinds of cloth.

Of all the domestic animals, none is so subject to various disorders as the sheep. Of these, one of the most extraordinary, as well as the most fatal, is the rot, owing to vast numbers of worms, of the genus fasciola, which are found in the liver and gall-bladder. They are of a flat form, of an oval shape, with slightly pointed extremities, and bear a general resemblance to the seeds of a gourd.

3. Ovis strepsiceros, Cretan sheep; this variety is principally found in the island of Crete, and is kept in several parts of Europe for the singularity of its appearance; the horns being very large, long, and twisted in the manner of a screw; those of the male are upright, those of the female at right angles to the head. This animal is ranked as a distinct species in the Systema Naturæ. See Plate Nat. Hist. fig. 306.

4. Ovis Guineensis, African sheep. This, which is sometimes termed the Cape sheep, and which is erroneously mentioned in Buffon's Natural History as of Indian extraction, is supposed to be most frequent in Guinea, and is distinguished from others by its remarkably meagre appearance, length of neck and limbs, pendant ears, and long arched or curved visage. It is covered rather with hair than wool, and has a pair of pendant hairy wattles beneath the neck, as in goats. The horns are small, and the tail long and lank. This variety is also considered as a distinct species in the twelfth edition of the Systema Naturæ. See Plate Nat. Hist. figs. 307, 308.

5. Ovis laticaudata, broad-tailed sheep; this extraordinary and awkward variety occurs in Syria, Barbary, and Ethiopia. It is also found in Tartary, Tibet, &c. Its general appearance, as to other parts of the body, scarcely differs from that of the European sheep, and in Tibet it is remarkable for the exquisite fineness of its wool. The tails of these sheep sometimes grow so large, long, and heavy, as to weigh, according to some reports, from fifteen to fifty pounds; and in order to enable the animal to graze with convenience, the shepherds are often obliged to put a board, furnished with small wheels, under the tail. This part of the sheep is of a substance resembling marrow, and is considered as a great delicacy.

6. Ovis pudu. This is a newly discovered species, having been first described by Molina, in his Natural History of Chili. He informs us that it is a native of the Andes;

that it is of a brown colour; about the size of a kid of half a year old; with very much the appearance of a goat; but with small smooth horns, bending outwards, and without any appearance of beard. It is of a gregarious nature, and when the snow falls on the upper parts of the mountains, descends into the valleys in large herds, to feed in the plains of Chili, at which time it is easily taken, and readily tamed. The female is without horns.

OUNCE, a little weight, the sixteenth part of a pound avoirdupois, and the twelfth part of a pound troy; the ounce avoirdupois is divided into eight drams, and the ounce troy into twenty pennyweights.

OUNCE. See FELIS.

OUTLAWRY, is being put out of the law, or out of the king's protection. It is a punishment inflicted for a contempt in refusing to be amenable to the process of the higher courts. By outlawry in civil actions, a person is put out of the protection of the law, so that he is not only incapable of suing for the redress of injuries, but may be imprisoned, and forfeits all his goods and chattels, and the profits of his land; his personal chattels immediately upon the outlawry, and his chattels real, and the profits of his lands, when found by inquisition. 1 Salk. 395.

It seems that originally process of outlawry only lay in treason and felony, and was afterwards extended to trespass of an enormous nature; but the process of outlawry at this day lies in all appeals, and in all indictments of conspiracy and deceit, or other crimes of a higher nature than trespass vi et armis; but it lies not in an action, nor on an indictment on a statute, unless it is given by such statute either expressly, as in the case of a præmunire; or impliedly, as in cases made treason or felony by statute; or where a recovery is given by an action in which such process lay before, as in case of forcible entry. Staundf. 192.

Process of outlawry. The exigent must be sued in the county where the party really resides, for there all actions were originally laid; and because outlawries were at first only for treason, felony, or very enormous trespasses, the process was to be executed at the *torn,* which is the sheriff's criminal court; and this held not only before the sheriff, but before the coroners, who were antient conservators of the peace, being the best men in each county, to preside with the sheriff in his court, and who pronounced the outlawry in the county-court on the parties being quintò exactus; and therefore antiently there was no occasion for any process to any other county than that in which the party actually resided. But the modern practice being different, the reader is referred to Tidd's Pract. K. B.

Of the reversal of outlawries. There are two ways of reversing an outlawry: first, by a writ of error returnable coram nobis; secondly by motion founded on a plea, averment, or suggestion of some matter apparent; as in respect of a supesedeas, omission of process, variance, or other matter apparent on the record.

OUTLICKER, in a ship, a small piece of timber made fast to the top of the poop, and standing out right astern. At the outmost end thereof is a hole, into which the standing part of the sheet is reeved.

OUTWORKS, in fortification, all those works made withoutside the ditch of a fortified place, to cover and defend it. See FORTIFICATION.

OX. See BOS.

OXALATS, salts formed by the oxalic acid. This genus of salts was first made known by Bergman, who described the greater number of them in his Dissertation on Oxalic Acid, published in 1776. These salts may be distinguished by the following properties: 1. When exposed to a red heat, their acid is decomposed and driven off, and the base only remains behind. 2. Lime-water precipitates a white powder from their solutions, provided no excess of acid is present. This powder is soluble in acetic acid, after being exposed to a red heat. 3. The earthy oxalats are in general nearly insoluble in water: the alkaline oxalats are capable of combining with an excess of acid, and forming superoxalats much less soluble than the oxalats. 4. The insoluble oxalats are rendered easily soluble by an excess of the more powerful acids.

OXALIC ACID. When nitric acid is poured upon sugar, and a moderate heat applied, the sugar soon melts, an effervescence ensues, a great quantity of nitrous gas and carbonic acid gas is emitted; and when the effervescence ceases, and the liquid in the retort is allowed to cool, a number of small transparent chrystals appear in it. These chrystals constitute a peculiar acid, which has received the name of oxalic acid, because it exists ready-formed, as Scheele has proved, in the oxalis acetosella, or woodsorrel. At first, however, it was called the acid of sugar, or the saccharine acid.

Oxalic acid is in the form of four-sided prisms, whose sides are alternately larger, and they are terminated at the extremities by two-sided summits. They are transparent, and of a fine white colour, with considerable lustre. They have a very acid taste, and redden vegetable blues.

When this chrystallized acid is exposed to heat in an open vessel, there arises a smoke from it, which affects disagreeably the nose and lungs. The residuum is a powder of a much whiter colour than the acid had been. By this process it loses three-tenths of its weight, but soon recovers them again on exposure to the air. When distilled, it first loses its water of chrystallization, then liquefies and becomes brown; a little phlegm passes over, a white saline crust sublimes, some of which passes into the receiver; but the greatest part of the acid is destroyed, leaving in the retort a mass one-fiftieth of the whole, which has an empyreumatic smell, blackens sulphuric acid, renders nitric acid yellow, and dissolves in muriatic acid without alteration. That part of the acid which sublimes is unaltered. When this acid is distilled a second time, it gives out a white smoke, which, condensing in the receiver, produces a colourless unchrystallizable acid, and a dark-coloured matter remains behind. During all this distillation, a vast quantity of elastic vapour makes its escape. From 279 grains of oxalic acid, Bergman obtained 109 cubic inches of gas, half of which was carbonic acid, and half carbureted hydrogen. Fontana, from an ounce of it, obtained 430 cubic inches of gas, one-third of which was carbonic acid, the rest carbureted hydrogen. From these facts, it is evident, that oxalic acid is composed of oxygen, hydrogen, and carbon.

The chrystals of oxalic acid are soluble in their own weight of boiling water. Water at the temperature of 65.7° dissolves half its weight of them. The specific gravity of the solution is 1.0593. One hundred parts of boiling alcohol dissolve 56 parts of these chrystals; but at a mean temperature only 40 parts. Liquid oxalic acid has a very a rid taste when it is concentrated, but a very agreeable acid taste when sufficiently diluted with water.

It changes all vegetable blues, except indigo, to a red. One grain of chrystallized acid, dissolved in 1920 grains of water, reddens the blue paper in which sugar-loaves are wrapt: one grain of it, dissolved in 3600 grains of water, reddens paper stained with turnsole. According to Morveau, one part of the chrystalline acid is sufficient to communicate a sensible acidity to 2633 parts of water.

Its fixity is such, that none of it is sublimed when water containing it in solution is raised to the boiling temperature.

Oxalic acid is not affected by exposure to the air, or to the action of oxygen gas. The effect of the simple combustibles on it has not been tried.

It is capable of oxidizing lead, copper, iron, tin, bismuth, nickel, cobalt, zinc, and manganese.

It does not act upon gold, silver, platina, nor mercury.

Oxalic acid combines with alkalies, earths, and metallic oxides, and forms salts known by the name of oxalats.

Muriatic and acetic acids dissolve oxalic acid, but without altering it. Sulphuric acid decomposes it partly by the assistance of heat, and a quantity of charcoal is formed. Nitric acid decomposes it at a boiling heat, and converts it into water and carbonic acid. From this result, and from the products obtained by distilling pure oxalic acid, it follows, that this acid is composed of oxygen, hydrogen, and carbon. Fourcroy informs us, that Vauquelin and he have ascertained that it is composed of

77	oxygen
13	carbon
10	hydrogen
100.	

But the experiments upon which this result is founded, have not been published; so that it is impossible to judge of their accuracy.

The affinities of oxalic acid, according to Bergman, are as follows:

Lime,
Barytes,
Strontian,
Magnesia,
Potass,
Soda,
Ammonia,
Alumina.

This acid is too expensive to be employed for the purposes of domestic economy; but it is extremely useful in chemistry to detect the presence of lime held in solution. For this purpose, either a little of the pure acid, or of the solution of oxalat of ammonia, is dropt into the liquid supposed to contain lime. If any is present, a white powder immediately precipitates. The reason of this is, that oxalat of lime is altogether insoluble, and oxalic acid in consequence is capable of taking lime from every other acid.

OXALIS, *woodsorrel*, a genus of the pentagynia order, in the decandria class of plants, and in the natural method ranking under the 14th order, gruinales. The calyx is pentaphyllous, the petals connected at the heels, the capsule pentagonal, and opening at the angles. There are 96 species; of which the common woodsorrel grows naturally in moist shady woods, and at the sides of hedges, in many parts of Britain, and is but seldom admitted into gardens. The roots are composed of many scaly joints, which propagate in great plenty. The leaves arise immediately from the roots upon single long footstalks, and are composed of three heart-shaped lobes. They are gratefully acid, and of use in the scurvy and other putrid disorders. The bulbous kinds from the Cape are elegant ornaments of the greenhouse.

OXIDE, any substance combined with oxygen, in a proportion not sufficient to produce acidity.

Oxygen is capable of combining with bodies usually in various proportions, constituting a variety of compounds with almost every substance with which it is capable of uniting. Now the whole of the compounds into which oxygen enters, may be divided into two sets: 1. Those which possess the properties of acids; and, 2. Those which are destitute of these properties. The first set of compounds are distinguished by the term acids; to the second, the term oxide has been appropriated. By oxide, then, is meant a substance composed of oxygen and some other body, and destitute of the properties which belong to acids. It is by no means uncommon to find a compound of the same base and oxygen belonging to both of these sets, according to the proportion of oxygen which enters into the compound. In all these cases, the smaller proportion of oxygen constitutes the oxide; the larger the acid. Hence it follows, that oxides always contain less oxygen than acids with the same base.

Oxygen combines with three distinct set of bodies, the simple combustibles, the incombustibles, and the metals, and forms oxides with every individual belonging to these sets. These oxides vary as the substance which constitutes the base; but all the oxides of the simple combustibles are combustible, except the oxide of hydrogen, which is a product of combustion; all the oxides of the simple incombustibles are supporters of combustion; and all the oxides of the metals are either products of combustion or supporters. Of course, the first set of oxides (except that of hydrogen) cannot be formed by combustion; neither can the second set; but part of the third set are formed by combustion, a part by the union of the oxygen of supporters without combustion.

Besides these oxides, which may be considered as simple, because they contain but one ingredient combined with oxygen, there is another set much more numerous than they, consisting of oxygen united at once with two or more simple substances. These bodies may be distinguished from the others by giving them the name of compound oxides.

Oxides are often distinguished according to the degree of oxygen they contain. Thus the protoxide or first oxide denotes a metal combined with the least portion of oxygen; deutoxide, or second oxide, a metal combined with two doses of oxygen; and when a metal has combined with as much oxygen as possible, the compound is called a peroxide.

Oxide, *carbonic*. When a mixture of purified charcoal and oxide of iron or zinc is exposed to a strong heat in an iron retort, the metallic oxide is gradually reduced, and during the reduction a great quantity of gas is evolved. This gas is a mixture of carbonic acid gas, and another which burns with a blue flame. This last is carbonic oxide.

OXYBAPHUS, a genus of plants as yet unclassed, nearly allied to the mirabilis, a native of Peru.

OXYGEN, in chemistry, a simple substance that enters into the composition of water and air. The term oxygen signifies that which generates or produces acids. This, one of the most characteristic properties of this body, was discovered by Dr. Priestley in 1774. It was at first called dephlogisticated air, and afterwards successively known by the names of eminently-respirable air, pure air, vital air, as long as it was not known that this aerial form is merely one of its states of combination; which, notwithstanding its frequency, and its being less impure in this than in any other condition, does not prevent its being concealed in other states; and more particularly as, by combining with many bodies, it loses this elastic state or appearance of air. As soon as this truth was well proved, and clearly explained by Lavoisier, the necessity was admitted of giving it a different name, which might be applicable to all the states in which it could exist, as well that of gas as of the liquid or solid form. Lavoisier first called it the oxygenous principle; and the French school having decided for the word oxygen, by admitting a simple change of termination in the first word proposed by Lavoisier, this name became generally adopted.

The effect of oxygen is of such importance, that its presence must be stated as the most indispensable condition of combustion; which would not otherwise take place. It truly constitutes the essential part of that process, because its most decided and extensive character is its indispensability in that process.

Oxygen, like many other natural bodies, is found in three states, but in neither of them is it alone or insulated. In the gaseous form it is dissolved in caloric; in the liquid and solid form it is combined with different substances, and can never exist concrete and pure without combination, like many other substances no less decomposable than itself. And though we can, in imagination, conceive it alone, insulated, pure, and in a solid state, experiment has never yet exhibited this fact. It is a discovery which still remains concealed in the bosom of nature; or may exist, ill understood, under the name of some substance yet unknown in our collections of minerals.

As oxygen is frequently contained in a more or less solid form in several natural fossils which have undergone combustion, and as it has much attraction for caloric, it is only required that some one of those fossils should be heated more or less, or penetrated with a great quantity of caloric, in order to disengage this principle, and obtain it in the form of air or gas. This is done by chemists to procure oxygen gas. They expose certain substances, particularly metals burned by nature or by art, to a fire of considerable activity in closed vessels, so disposed as to conduct and receive, under inverted jars, the elastic fluid intended to be collected. The burned matter passes again to a combustible state; and the oxygen which gave it the burned state, being separated and fused by caloric, for which it has a great attraction, becomes developed in the form of gas. It is the product of a true combustion.

Of the two bodies which form oxygen gas, the caloric, which is the solvent, and gives it the state of invisibility and elastic fluid, not being ponderable; the solidifiable base which is dissolved, or oxygen, being the only ponderable and fixable body in all the substances with which this gas can combine; and chemists having no other means of obtaining oxygen in a simpler state than that of gas, in which they use it for a great number of operations or combinations; many of them are habituated to denote this gas by the simple name of oxygen. This is, nevertheless, an error of nomenclature, and inimical to the perspicuity of chemical doctrine; because the word oxygen ought only to be used to denote the base of this gas considered alone, or in all the possible states, but parcularly in the numerous combinations wherein it possesses the liquid or solid state.

Oxygen gas. See Air.

OXYMEL, in pharmacy, a composition of vinegar and honey.

OXYMURIATIC ACID. This acid was discovered by Scheele in 1774, during his experiments on manganese. He gave it the name of dephlogisticated muriatic acid, from the supposition that it is muriatic acid deprived of phlogiston. The French chemists, after its composition had been ascertained, called it oxygenated muriatic acid; which unwieldy appellation Kirwan has happily contracted into oxymuriatic acid.

It may be procured by the following process: Put into a tubulated retort a mixture of three parts of common salt, and one part of the black oxide of manganese in powder. Place the retort in the sand-bath of a furnace, plunge its beak into a small water-trough, and lute a bent funnel into its mouth. When the mixture has acquired a moderate heat, pour into it at intervals through the bent funnel two parts of sulphuric acid, which ought to be somewhat diluted with water. An effervescence ensues; a yellow-coloured gas issues from the retort, which may be received in large phials fitted with ground stoppers.

Oxymuriatic acid gas is of a yellowish-green colour. Its odour is intolerably acrid and suffocating. It cannot be breathed without proving fatal. The death of the ingenious and industrious Pelletier, whose chemical labours have been so useful to the world, was occasioned by his attempting to respire it. A consumption was the consequence of this attempt, which, in a short time, proved fatal. When atmospheric air containing a mixture of it is breathed, it occasions a violent and almost convulsive cough, attended with much pain in the chest. This cough usually continues to return at intervals for a day or two, and is accompanied with a copious expectoration.

It is capable of supporting combustion; in many cases even more capable than common air. When a burning taper is plunged into it, the flame is diminished, and acquires a very red colour; a great quantity of smoke is emitted, and at the same time the taper consumes much more rapidly than in common air. The facility with which bodies take fire in this gas, seems to depend on the ease with which it parts with its oxygen.

This gas is neither altered by exposure to light nor to caloric. It passes unaltered through red-hot porcelain tubes.

It does not unite readily with water. Scheele found, that after standing 12 hours over water, four-fifths of the gas were absorbed: the remainder was common air, which no doubt had been contained in the vessel before the operation.

It renders vegetable colours white; and not red, as other acids do; and the colour thus destroyed can neither be restored by acids nor alkalies. It has the same effects on yellow wax. If the quantity of vegetable colours to which it is applied is sufficiently great, it is found reduced to the state of common muriatic acid. Hence it is evident, that it destroys these colours by communicating oxygen. This property has rendered oxymuriatic acid a very important article in bleaching.

When a mixture of oxymuriatic acid gas and hydrogen gas is made to pass through a red-hot porcelain tube, a violent detonation takes place. By electricity a feeble explosion is produced.

When melted sulphur is plunged into it, inflammation also takes place, and the sulphur is converted into sulphuric acid; but cold sulphur, though it is partly acidified by this gas, does not take fire in it.

When phosphorus is plunged into this gas, it immediately takes fire, burns with considerable splendour, and is converted into phosphoric acid.

Oxymuriatic acid oxidizes all the metals without the assistance of heat. Several of them take fire as soon as they come into contact with the gas. All that is necessary is, to throw a quantity of the metal reduced to a fine powder into a vessel filled with the gas. The inflammation takes place immediately; the metal is oxidized; while the acid, decomposed and reduced to common muriatic acid, combines with the oxide, and forms a muriat. Arsenic burns in oxymuriatic acid gas with a blue and green flame; bismuth, with a lively bluish flame; nickel, with a white flame, bordering on yellow; cobalt, with a white flame, approaching to blue; zinc, with a lively white flame; tin, with a feeble bluish flame; lead, with a sparkling white flame; copper and iron, with a red flame. Several of the metallic sulphurets, as cinnabar, realgar, sulphuret of antimony, take fire when thrown in powder into this gas.

When oxymuriatic acid gas and ammoniacal gas are mixed together, a rapid combustion, attended with a white flame, instantly takes place; both the gases are decomposed, water is formed, while azotic gas and muriatic acid are evolved. The same phenomena are apparent, though in a smaller degree, when liquid ammonia is poured into the acid gas. The same decomposition takes place, though both the acid and alkali are in a liquid state. If four-fifths of a glass tube are filled with oxymuriatic acid, and the remaining fifth with ammonia, and the tube is then inverted over water, an effervescence ensues, and azotic gas is extricated. It was by a similar experiment that Berthollet demonstrated the composition of ammonia.

Oxymuriatic acid is composed of

84	muriatic acid
16	oxygen
100.	

Though oxymuriatic acid has hitherto been placed among acids by chemists, it does not possess a single property which characterises that class of bodies. Its taste is not acid but astringent; it does not convert vegetable blues to red, but destroys them; it combines very sparingly with water, and is incapable of combining with alkalies, earths, or metallic oxides. It ought, therefore, to be placed among the oxides rather than the acids.

OYER OF DEED, is when a man brings an action upon a deed, bond, &c. and the defendant appears and prays that he may hear the bond, &c. wherewith he is charged, and the same shall be allowed him: and he is not bound to plead till he has it, paying for the copy of it.

The time allowed for the plaintiff to give oyer of a deed, &c. to the defendant, is two days exclusive after it is demanded. Carth. 454. 2 Durnf. & East, 40.

OYER AND TERMINER, is a court held by virtue of the king's commission, to hear and determine all treasons, felonies, and misdemeanors. This commission is usually directed to two of the judges of the circuit, and several gentlemen of the county; but the judges only are of the quorum, so that the rest cannot act without them. 4 Black. 269. See ASSIZES.

OYES, or OYEZ, signifies hear ye; and is frequently used by the cryers in our courts on making proclamation, or to enjoin silence.

OYSTER. See OSTREA.

OZÆNA, a malignant ulcer of the nose, frequently accompanied with a caries of all the bones of that part. See SURGERY.

OZOPHYLLUM, a genus of the class and order monadelphia pentandria. It is one-styled; calyx five-toothed; petals five, long; filaments sheathing; the style five-toothed at top; teeth antheriferous; stigma one; capsules five-celled. There is one species, a native of Guiana.

P

P, the fifteenth letter of the alphabet, as an abbreviature, stands for Publius, pondo, &c.; PA. DIG. for patricia dignitas; P. C. for patres conscripti; P. F. for Publii filius; P. P. for propositum, or propositum publice; P. R. for populus Romanus; PR.S. for prætoris sententia; and PRS. P. for præses provinciæ. In the Italian music, P. stands for piano, or softly; P.P. for piu piano, *i. e.* more softly; and PPP. for pianissimo, or very softly. Among astronomers, P. M. is used to denote post meridiem, or afternoon; and sometimes for post mane, *i. e.* after midnight. As a numeral, P. signifies the same as G, viz. 400; and with a dash over it, thus G, 400,000. Among physicians, P. denotes pugil or the eighth part of a handful; P. Æ. partes æquales, or equal parts of the ingredients.

PACE, *passus*, a measure taken from the space between the two feet of a man in walking; usually reckoned two feet and a half, and in some men a yard or three feet.

The geometrical pace is five feet; and 60,000 such paces make one degree of the equator.

PACK, in commerce, denotes a quantity of goods, made up in loads or bales for carriage. A pack of wool is 17 stone and two pounds, or a horse's load.

PACKERS, persons whose employment it is to pack up all goods intended for exportation; which they do for the great trading companies and merchants of London, and are answerable if the goods receive any damage through bad package.

PACOS. See CAMELUS.

PÆDERIA, a genus of the pentandria monogynia class and order. It is contorted; berry void, brittle, two-seeded; style bifid. There are two species, climbers of the East Indies.

PÆDEROTA, a genus of the monogynia order, in the pentandria class of plants, and in the natural method ranking under the 30th order, contortæ. The berry is empty, brittle, and dispermous; the style bifid. There are three species.

PÆONIA, *peony*, a genus of the digynia order, in the polyandria class of plants, and in the natural method ranking under the 26th order, multisiliquæ. The calyx is pentaphyllous; the petals five; there are no styles; the capsules are polyspermous. There are five species, most of them hardy. They are large herbaceous flowery perennials, with tuberous roots, sending up strong annual stalks from one to three feet in height, terminated by very large flowers of a beautiful red colour, and much larger than any rose. The common officinal, or male peony, is also remarkable for its capsules turning backward, opening and displaying their red inside, together with the numerous seeds in a singularly agreeable order, appearing very ornamental after the flower is past. The plant may be propagated either by parting the root or by seed. This plant was formerly celebrated in nervous distempers, but the present practice pays very little regard to it.

PAGE, a youth of state retained in the family of a prince or great personage, as an honourable servant, to attend in visits of ceremony, carry messages, bear up trains, robes, &c. and at the same time to have a genteel education, and learn his exercises. The pages in the king's household are various, and have various offices assigned them, as pages of honour, pages of the presence-chamber, pages of the back stairs, &c.

PAGOD, or PAGODA, a name whereby the East Indians call the temple in which they worship their gods. The pagod usually consists of three parts; the first is a vaulted roof, supported on stone or marble columns: it is adorned with images; and, being open, all persons without distinction are allowed to enter it. The second part is filled with grotesque and monstrous figures, and no person is allowed to enter it but the bramins themselves. The third is a kind of chancel, in which the statue of the deity is placed. It is shut up with a very strong gate.

PAGOD, or PAGODA, is also the name of a gold or silver coin, current in several parts of the East Indies, value 5*s*.

PAINTING, is the art of representing all objects of nature visibly, by lines and colours on a plain surface. It has also the power of expressing by the same means conceptions and images of the mind which do not actually exist in any of the usual forms of nature. It is to be considered as an art displaying either conjointly or separately the powers of imagination and imitation: and may be divided into invention, which regards the original thought or conception of the subject; and into composition, design, and colouring, which regard the execution of the work.

Invention consists generally in the choice of such subjects as are best calculated to answer some great and interesting end; and particularly in discovering or selecting such subjects as are capable of being most appropriately expressed by painting, and of producing a powerful effect by such means as are distinctively placed within the compass of that art.

Composition regards the arrangement of the subject both as to forms, and to the general effects of light and shade, and of colour. It comprehends the general distribution and grouping of the figures, their combination or contrast, the choice of attitudes, the disposal of draperies, the situation of the scene itself, as well as the distribution and connection of all the various parts of scenery and ornament.

The important objects which design embraces, will be found fully explained under that article. See DESIGN.

Colouring regards, first, the infinite variety of hues with which nature distinguishes her forms, agreeably to the degree and mixture of the rays of light which their surfaces reflect; and, secondly, the distribution, apposition, and accompaniment, of various hues or tints, so as to produce the effect most pleasing to the sight, a circumstance in which nature not always delights. It embraces also the light and shade of objects, as far as by the diminution or increase of these the harmony of tints before-mentioned can be effected; but that mixed effect of colour and of light and shade which is denominated chiaro-scuro, is more justly regarded as a branch of composition.

Art of painting. The art of painting is justly ranked among the highest of that class of arts which are denominated liberal. Its tendency and powers are congenial with those of poetry, and it has of course been considered as an employment worthy of men in the most elevated ranks of life. The honours with which it has been distinguished in various countries, will be found in the history of its professors.

We shall proceed, in consistence with a general plan, to describe, first, the means by which the student may hope to forward his progress in this admirable but difficult art. We shall then state the different branches of painting, and the methods of practice; and shall lastly add a summary of its history in all ages and countries.

Course and methods of study requisite to attain the art of painting.

The process of study requisite for the attainment of the art of painting, has been in part already described under the article DESIGN; the knowledge of design being, as was there said, the basis of painting, and its various attainments the necessary steps by which the painter must commence his advance in the art. The student having completed the various studies which lead to excellence in drawing, must proceed to transfer the principles he has learned to his canvas; and, before he can arrive at eminence, must acquire a complete mastery of the new materials in which he is to display at once the stores of his mind and the skill of his hand. For this purpose, he must add to the knowledge he already possesses, the study of colours and colouring in all their branches. It is the knowledge of this department of art which peculiarly characterizes the profession he is about to undertake. The various branches of design have formed the commencement of his studies, and he may be supposed a perfect master of them; but these alone cannot constitute him a painter; neither can he acquire that title by the knowledge of every rule of invention or composition. If we consider a painter in regard of these last powers of skill, we rank him with the poet or the draughtsman; if in regard of anatomic knowledge or perspective, we confound him with the anatomist or the mathematician; if in regard of symmetry, grace, and proportions of forms, we cannot distinguish him from the geometer or the sculptor. The painter, who is supposed the perfect imitator of nature, necessarily makes colouring his chief object, since he only considers nature as she is imitable: she is only imitable by him as she is visible; and she is only visible as she is coloured.

Although the perfect idea, therefore, of a painter depends on invention, composition, design, and colouring, conjointly, yet it is by the last of these only that he can establish a special idea of his art, since by this we distinguish him from such other artists as have for their object the various powers which can be expressed by design (whose art cannot come up to that perfect imitation of nature, which is within the scope of painting); and by this only we can be decidedly understood to speak of a painter.

To this it is to be added, that as colouring specifically distinguishes the art of the painter from all the other arts of design, so it is the ultimate accomplishment of all his studies in the art of painting.

We shall, therefore, first treat of colouring, and proceed to consider more minutely the component parts which form the art of colouring.

Colouring. Colouring is that mode of art by which the artist imitates the appearance of colours in all natural objects, and gives to artificial objects those hues which are most calculated to please or to deceive the sight.

It is the duty of the colourist to consider, that as there are two sorts of objects, the natural or real, and the artificial or painted, so there are also two sorts of colours, viz. the natural, or that which makes all the objects in nature visible to us, and the artificial, or that which, by a judicious mixture of simple colours, imitates those natural ones in all their various situations and circumstances.

The painter must first endeavour to acquire a perfect knowledge of these two sorts of colours; of the natural, in order to distinguish with precision which of them he ought to imitate; and of the artificial, in order to compose the tint most proper for representing the natural colour. These acquirements include the study of dioptrics, or that part of optics which has for its object the nature of light and colours, and an acquaintance at least with the general principles of chemistry. (See OPTICS.) He will learn also that the natural colour is of three sorts: 1st, the true colour of the object; 2d, the reflected colour; 3d, the colour of the light incidental to the object. In the artificial colours, he will distinguish their force and softness separately and by comparison, in order that he may use a proper judgment in heightening or attenuating them, according as his subject may require.

To this end he will also consider, that a picture is, for the most part, a flat superficies; that, some time after the colours are laid on, they necessarily lose their freshness; and that the distance at which a picture is viewed takes from it much of its brightness and vigour; and it is therefore impossible to guard against these drawbacks on the effect of his pencil, without a complete mastery of that artifice which is the chief object of the art of colouring.

Although imitation is the principal aim of colouring, the painter must by no means be the slave of natural objects, but the judge and judicious imitator of them: he must not imitate all the colours which present themselves indifferently to his eye; but he must chuse the most proper for his purpose, and add or temper with others, to complete the beauty of effect in his work. He must sometimes abate the vivacity of life, and sometimes strive to heighten it by superior force and brightness of colours, in order to convey to the eye with precision and truth the spirit and real character of the object. There are few, and those only among the greatest painters, who have arrived at the perfect management of this difficult part of art.

On the apposition of colours, and on the knowledge of chiaro-scuro, depends all the harmony of colouring. In what that happy arrangement of colours consists, which produces effects delightful to the eye, no rules can pretend to ascertain. If the source of information in this point is not in the mind of the painter, he will in vain seek for it elsewhere. Improvement, however, may, and must, be superadded to natural discrimination: to acquire the necessary improvement, he will find the best school in the works of those great masters who have possessed the power of colouring in an eminent degree. Such are Titian and Rubens. But he must be careful that, in studying even these great examples of the art, he does not forget that he is only learning from them the road to nature, the final source of his imitation.

Of the few maxims which can be offered on the subject of colouring, the following are the least questionable:

We must learn to view nature to advantage, in order to represent her well. There are two manners of colouring: the one depending on habit, the other on the true knowledge of colours. The first is confined, the second unlimited.

The harmony of nature in her colours arises from objects participating of one another by reflection; for there is no light which does not strike some body; nor is there any enlightened body which does not reflect its light and colour at the same time, in proportion to the force of the light, and according to the nature of the colour. This participation of reflection in light and colour, constitutes that union of colouring which it is the business of the painter to imitate.

This desirable union of colour is sometimes considerably aided in pictures by the process of glazing; that is, by the use of colours which, having little body, are diaphonous; and are, by means of a light brush or pencil, passed over (or, as painters express it, *scumbled* over) such parts of the work as are unpleasantly staring or otherwise discordant. This use of transparent colour is by some called toning, or tuning; and probably affords the justest explanation of the well-known passage in Pliny, where he speaks of the *atramentum* used by one of the antient painters to give harmony and sweetness to his pictures.

Variety of tints, very nearly of the same tone, employed in the same figure, and often upon the same part, with moderation, contribute much to harmony.

The turn of the parts, and the outlines which insensibly melt into their grounds and artfully disappear, bind the objects together, and preserve them in union; as they seem to conduct the eye beyond what it sees, and persuade it that it sees what it really does not see, or at least that it conceives that continuity which the extremities of the objects conceal.

Any loading or overcharging of colouring, for whatever purpose it is used, must be so discreetly managed, as not to destroy the character of the object.

The repetition of the same colour in a picture is to be avoided, unless where it serves to connect the various masses of a composition. The eye becomes tired with viewing the same object: it loves variety artfully presented to it.

The apparent value of colours in a picture (as in all things) arises from comparison.

Several colours which, placed unmixed by one another, have a kind of aerial brightness, when mixed together, produce a disagreeable earthy colour: for instance, ultramarine with fine yellow, or fine vermilion.

Colours which by mixture lose strength and become harmonious, are called broken colours, and contribute as greatly to the sweetness and softness of tones in pictures as they subtract from their brightness.

Chiaro-scuro. The knowledge of lights and shades evidently forms a part of that essential distinction of painting, which we have just described under the head of colouring, and is requisite to that part of colouring which refers to composition. But the incidence of particular lights and shades on bodies placed on certain planes and exposed to certain lights (a knowledge to be gained from the study of perspective), is a very small part of that general knowledge of effect which is denominated chiaro-scuro, by which is meant the art of skilfully distributing the lights and shades which ought to appear in a picture as well for the repose as satisfaction of the eye. The incidence of light may be demonstrated by lines supposed to be drawn from the source of that light to the body enlightened; whereas the chiaro-scuro depends entirely on the painter's imagination, who, as he invents the objects, may dispose them to receive such lights and shades as he proposes for his picture, and introduce such accidents of colour as he deems most advantageous to the effect of the whole.

Chiaro-scuro, therefore, demands a perfect knowledge of the effects of light and shade, of aerial perspective, of the proportional force of colours, or of those qualities by which they appear to advance to, or recede from, the eye, and of their various degrees of transparency or opaqueness.

The art of chiaro-scuro consists, 1st, in connecting and combining the figures or objects of a composition in such masses of light and of shade, as are both the most pleasing to the eye and the best calculated for the just developement and display of the subject. 2dly, In assigning to each object the colour most corresponding (on account of the force or qualities above-mentioned) to its respective place in the general mass or group, and at the same time best harmonizing with the other colours of the picture, either by its natural and proper tone, or by the reflected hues which it receives from adjoining or surrounding objects. The beauty of these reflexes depends on the skilful adaptation of transparent or opaque colours. 3dly, In the judicious introduction of such accidents as contribute to strengthen the general effect and character of the work. It is on chiaro-scuro, says Mengs, that depends the expression of the character of a picture, whether it is gay or gloomy, cheerful or solemn.

The distribution of objects forms the masses of chiara-scuro, by combining or connecting their lights and shades in such a manner as to prevent the eye from wandering confusedly over the work. Titian exemplified this precept in the instance of a bunch of grapes, of which each grape, if seen separately, would have its light and shade in a similar degree, and thus distracting the sight, would produce a tiresome confusion; but when collected in one bunch, and becoming but one mass of light and shade, the eye is capable of embracing them all together as a single object.

The distribution of colours has an evident power of uniting the masses of light and shade; as the painter may for instance introduce a figure clothed in dark-brown drapery, so nearly approaching in colour to the shade of any two objects between which it is placed, that they will appear but one mass, and will be embraced by the eye as such. The same effect will be produced by the apposition of similar or accordant colours in various objects.

The distribution of accidents, by which accessory lights or shades are introduced, has the same obvious tendency to unite the masses of visible colour. Torches, clouds, &c. are comprized under this head.

The art of chiaro-scuro is that which, of all others comprehended under the general head of painting, appears to have the greatest power of attracting the eye of the spectator, and of exciting the admiration of the artist in particular.

In the same manner that we have here endeavoured to define the general principles of that distinctive branch of the painter's art called colouring, and as we have before fully described the requisite progress of study in drawing or design, we shall now proceed to the remaining branch, composition; and afterwards add a few words respecting invention.

Composition. Composition may be divided into the general distribution of objects, the grouping, the choice of attitudes, the contrast, the cast of draperies, and the management of the back-ground or the connection of the whole effect.

In composition, as far as regards the general distribution of objects, the painter ought to contrive that the spectator may, at the first sight, be struck with the general character of the subject, or at least may comprehend its principal scope. This effect is most readily produced by placing the most essential figures in the most conspicuous places, provided it can be done without violence or impropriety. Besides this distinctness in the general expression of the subject, the beauty of the composition will depend on the variety, connection, and contrast, displayed in the distribution of objects; provided, in like manner, that these are conformable to the nature of the subject, whether gay, familiar, full of motion and hurry, or still, solemn, and melancholy.

The grouping regards both design and chiaro-scuro. In the former, it respects the figures principally concerned in the expression of the subject, which must necessarily be near to, or distant from, one another, as their actions, conversations, or other mutual relations, require. In the latter, it regards those masses which are formed from objects which may be properly arranged together, and those effects of light and shade which are formed in consequence of such assemblage or union. These are the points to which the attention must be principally and diligently directed in forming the groups of a composition.

The choice of attitudes is the principal subordinate division of grouping. Whatever attitude is given, it must not only contribute its due portion to the completion of the group, but the greatest care must be taken by the painter, that it does not appear to be introduced for that purpose merely. It must be appropriate to the character of the individual figure, and expressive of its requisite action; and it must, at the same time, combine whatever beauty of form can be shewn by such a selection of turns or views of the body, as the necessary circumstances will admit. The knowledge of generic characters, under the various modifications of sex, age, and condition; of the various operations of the passions in the human mind; and a thorough acquaintance with the circumstances of the history or other subjects to be represented; are the best guides to a good choice of attitudes.

To the effect produced by well-chosen attitudes, contrast gives the most powerful aid. Contrast has been already defined (see Contrast); and it is only to be observed here that in composition it extends not to human figures only, but to objects of every kind, animate or inanimate, and also to the effects of light or chiaro-scuro.

Of draperies, and the proper modes of casting or disposing them, notice has been taken under the article Drawing.

The management of the back-ground, or connection of the general effect, is, of all other parts of composition, at once the most difficult to be defined or performed. It consists in the general accordance and subordination of objects with and to one another, so that they shall all concur to constitute but one single object. It is to the whole what the grouping of lines, forms, and chiaro-scuro, is to a part. It is effected by a due combination of lights and shades, by an union of colours, and by such oppositions or contrasts as are sufficient to relieve the distinct groups, and to give repose to the eye. Amidst several groups (if the picture consists of such), it requires that one should be justly predominant in force and colour, and that all detached objects should be so united with their respective grounds as to form together one general mass of repose for the support of the principal object.

The satisfaction of the eye is the ultimate purpose of this difficult part of composition.

Invention. It now remains to enlarge on the most arduous attainment of the painter, and which we have placed the last in the order of his studies, because it is that which gives the highest character to the artist, as it affords the greatest opportunities of displaying the powers of his mind.

Invention comprises every kind of subject which can be represented to sight; but it is generally divided into historical, allegorical, and mystical.

Invention simply historical, is the selection of such objects as plainly relate to or represent a subject. Its degrees are more or less valuable according to its matter or subject, and its requisite properties are fidelity and perspicuity. It extends also to the introduction of all such embellishments as are consistent and congenial with the history represented, in the same manner as in poetry. The same illustration by collateral erudition, the same enlivening by incidental ornament, the same blending of poetic imagery (not over-stepping truth), is admired in the painter as in the poet.

The cartoons of Raffaelle are among the works which present the finest examples of this species of invention. The battles of Constantine, and some others by the same master, in the Vatican, are equally excellent.

Allegorical invention is a choice of objects which serve to represent either wholly or partly what they are not; and of which the expression arises from illusion. Calumny dragged in, at the feet of Truth, as described by Lucian, and sketched by Raffaelle, is wholly of this class. Such also is Hercules placed between Virtue and Pleasure (generally called the Choice of Hercules); and such also is the picture of the School of Athens, by Raffaelle, in which many persons of various times, countries, and conditions, are brought together, to represent the various modes of philosophy.

Other works are partly allegorical and partly historical; in which the spectator easily distinguishes the figures purely historical from others mixed with them in the same picture, and entirely allegorical. Such are the well-known pictures of the history of Mary de Medici, painted by Rubens.

The first great requisite of allegorical painting is, that it be intelligible. An allegory not understood, is a loss of labour both to painter and spectator. For this purpose, it must, in general, consist of such symbols as are established on good authority, or, if new, are obvious to the mind.

In addition to this first requisite, the proper choice of allegory demands, either that the subject could in no other way be represented, or that it could not be represented by historical invention in an equal degree of force and beauty.

Mystical invention respects the expression of such ideas as are inculcated in our minds by the precepts of religion. The paintings in the Capella Sistina at Rome, by Michael Angelo, exhibit an illustrious instance of this kind of invention; and the student (with certain modifications) can enter no better school of this part of art. The Transfiguration of our Saviour, by Raffaelle, the Annunciation, Holy Families, &c. of numerous painters, are of the same kind.

The style of mystical painting is sometimes familiar and tender, as in subjects of the Holy Family, but chiefly majestic and elevated.

We have thus accompanied the painter, and slightly, but it is hoped justly, traced his path, through the long course of his studies; in the prosecution of which he must himself contribute the fullest share of unwearied diligence and attention. Nor are his pursuits to be considered as bounded by the rules which have been given. Enough remains behind to exercise both his industry and genius.

Beyond the complete possession of the various component parts of art which have been enumerated, expression, in all its distinct powers of vivacity, justness, and delicacy, calls for every exertion of talent. See Expression. And to all this, in order to attain perfection, must be superadded the rare and transcendant charm of grace, that indefinable excellence which no painters are allowed to have reached, except Apelles, Raffaelle, and Correggio.

Of the different classes of painting.

Painting is chiefly divided into historical (comprehending allegorical and mystical), grotesque, portrait, fancy, animals, fruits and flowers, battles, landscape, sea-views, architecture, still life. The subordinate divisions of all these are endless.

The first has been sufficiently spoken of under the head of *invention*, in the present article.

Grotesque painting being also already explained under its proper article, it is only necessary here to add, that the finest examples of this species are to be found in the celebrated Loggia of the Vatican palace at Rome, painted from the designs of Raffaelle, and in the ceiling of the portico of the Capitol, carved from those of Michael Angelo.

Of portrait, as being a branch of painting to which our country is peculiarly addicted, it is requisite to give a more detailed account.

Portraiture. If the accurate imitation of nature is, on any occasion, capable of forming the principal merit of a picture, it must certainly be in portraiture, which not only represents a man in general, but such an one as may be distinguished from all other men. The greatest perfection of a portrait is extreme likeness, and the greatest fault is the resemblance of a person for whom it was not designed, unless we are inclined to except a still more grievous defect, viz. the want of resemblance to any person whatever. The resemblance of men to one another, is indeed frequently found in living nature, but it is seldom or never so complete and entire, but that some particular turn or view of the face will betray the difference; and it is the business of the artist ever to discriminate, and to appropriate to his pencil, those peculiar features, lines, and turns of the face, the representation of which will effectually convey to the spectator the distinct especial idea of the person whose portrait is set before him.

Various difficulties attend, and not seldom impede, the execution of this task. It is true, that there is not a single person in the world, of whatever age, sex, or condition, who has not a peculiar character both in body and face; but it is also the essential duty of portraiture, that it not only imitate what we see in nature, but that it exhibit such views of nature as are confessedly the most advantageous to the person represented. The moment that the idea raised by the sight of the portrait is inferior to that raised by the sight of the person, the labour of the artist sinks into the debasing region of caricature.

Likeness, however, being the essence of portrait, it is unquestionably the part of the painter to imitate defects as well as beauties, since, by this means, the resemblance will be more complete. He is only to be aware that he strictly preserves that balance which constitutes the character of the object. It has been sometimes suggested by those who are more willing to court favour than fame, that all appearances of deformity, when the air, temper, and general likeness of the face, can be discerned without them, ought to be omitted or corrected in portraiture; but this must be done at least with considerable discretion; for, by too strenuous endeavours to correct, nature, it is always found that the painter insensibly falls into a habit of giving a general air to his portraits, as suitable to one person as to another, or perhaps properly suited to none.

In the portraits of particularly distinguished characters, of men illustrious either for rank, virtue, great actions, or exalted talents, exactitude of representation, whether in beauties or defects, cannot be too closely pursued. Portraits of such persons are to become the standing monuments of their high name to posterity; and in this instance every thing is precious that is faithful.

The resemblance, as well as every other excellence, of a portrait, depends on feature, expression, air, colouring, attitude, and attire.

The features require to be carefully examined and studied by inspection in many different views, so that at the moment when the painter puts his pencil to the canvas, he may be possessed not only of the apparent form of each particular feature in the view in which he represents it, but of its real and characteristic form also, the full expression of which is not discernible in every view. Each particular feature should appear so distinctly shaped, as that an exact model of the real head could be formed from the picture, if requisite; and they must be at the same time so blended in the general mass of the face, that no one shall obtrude itself on the eye beyond the rest. The peculiar mode of touch, or execution, whereby each feature is best discriminated, can only be learned from practice, and the attentive study of the best masters.

For expression, the student is referred to the general rules already given under that article. See Expression. In addition to which, it is requisite to observe, that the greatest care is to be used in a portrait, in order that the expression of the features is uniform and consistent with each other. Errors in this respect are among the most frequent in portrait-painting. The mouth is sometimes represented smiling, while the eyes are sad, and vice versa, &c. The painter must therefore constantly bear in mind the general idea that he has formed of the countenance he intends to express, and must be watchful of the corresponding forms of the features in moments of similar expression. The portraits of Titian and Raffaelle are pre-eminent in this point. The same remark here applied to the various minute parts of the face may be extended to all the larger portions of the figure. The same expression must be clearly perceived in the motion or direction of the hands, arms, legs, and body, that appears to prevail in the countenance and turn of the head. It is this combination only which can give the exact resemblance of the expression of nature, under the impulse of which no particular limb ever deviates from the general intention of the whole body. See Expression.

The air principally regards the lines of the face or figure, the attire of the head or person, and the stature or make of the general form.

The proper lines of the face or figure depend on accuracy of drawing, and an entire agreement of the parts of the same form with one another. Nothing so entirely disguises or alters the appearance of an individual person as the change of head-dress, whether it is the adjustment of hair or attire. The greatest attention, therefore, is to be used in adapting the arrangement of this part of the portrait to the general character of the person represented.

The stature and make, in the same manner, contribute to the force of resemblance (as the least observation on nature will teach us), and never fail considerably to influence the air of the person. It is therefore requisite for the truth of portrait, that this part of the picture should be as faithfully studied from the sitter as the face itself.

With regard to the methods of proceeding in the execution of a portrait, they have been, and are, so exceedingly various in various masters, that a discussion of them would lead to an endless labyrinth. We shall, however, select a curious statement of Vandyck's mode of practice, in the latter time of his eminence in this branch of painting, as it is related by Du Piles, on the authority of Jabac, a man well known to all the lovers of the fine arts, and a friend of Vandyck, who thrice painted his portrait:

"Vandyck's custom, as Jabac told me, was this: he appointed both the day and hour for the person's sitting, and worked not above an hour on any portrait, either in rubbing in or finishing; so that as soon as the clock informed him that the hour was out, he rose, and dismissed his sitter, appointing another hour on some other day. His servant then came to clean his pencils, and brought a fresh pallet, while he was receiving another sitter, whose day and hour he had also appointed.

"After having lightly dead-coloured the face, he put the sitter into some attitude which he had before contrived; and on grey paper, with white and black crayons, he designed in a quarter of an hour his shape and drapery, which he disposed in a grand manner, and an exquisite taste. This drawing he gave to skilful persons whom he kept about him, to paint from the sitter's own clothes, which at Vandyck's request were sent to him for that purpose. When his disciples had done the most they could to these draperies, he lightly went over them again; and so in a little time, by his great knowledge, displayed the art and truth which we at this day admire in them."

Nothing varies more quickly, more discernibly, or more frequently, than the colour of a sitter's face. Great care must therefore be taken to establish an uniform judgment of the sitter in this respect also; for the colouring of the skin or complexion, being an effusion of nature, tending to discover the true tempers of persons, exactness of imitation here becomes essential to the exhibition of character. It may be therefore expedient to watch the first moments of the appearance of colour in the sitter, who, sooner or later, from a continuance in one posture, loses those spirits, which, at his first sitting down, gave to every part of the face a livelier and fresher hue. There is no other point of painting in which the paradox may be more truly asserted, "that the painter who only paints what he sees will never arrive at perfect imitation."

The other classes of painting are sufficiently denoted by their names, excepting the last, viz. *still life*, of which it may be requisite to add that the term is applied to all inanimate objects, but chiefly to household furniture, ornaments, and instruments of use, &c. &c. &c.

Modes and materials of painting.

The different modes of painting now in use are:

Oil painting; preferable to all other methods, as it admits of a perfect gradation of tints in the most durable of all materials, except those of

Mosaic painting; in which an imitation of objects is produced by the junction of a great number of small pieces of natural marble of different colours fixed in stucco, a mortar, so that if the mortar is well prepared, the monuments of this art may descend to the most remote ages. Some of the works of the great Italian masters have been excellently copied in mosaic, and are to be seen in St. Peter's church at Rome.

Fresco painting; which is performed with colours diluted in water, and laid on a wall newly plaistered, with which they incorporate, and are sometimes as durable as the stucco itself.

Crayon painting; in which colours, either simple or compound, are ground in water mixed with gum, and made into small rolls of a hard paste, which are then used on paper or parchment.

Miniature painting; which consists of colours prepared with water or gum, and laid on vellum or ivory. It is of course confined to works of a very small size.

Enamel painting; which is performed on copper or gold, with mineral colours, dried by fire. This method is also very durable.

Wax, or encaustic painting; performed by the mixture of wax with the varnish and colours.

Painting on glass, too well known to need description, and performed by various methods.

Painting in distemper; which is with colours mixed with size, whites of eggs, or any thin glutinous substance, and used on paper, linen, silk, board, or wall.

Painting in water-colours, more properly called limning: it is performed with colours mixed with water, gum, size, paste, &c. on paper, silk, and various other materials.

To these is to be added elydoric painting, consisting of a mixed use of oil-colours and water.

For a full account of some of these methods, see their repesctive articles in this work. Those of which a farther explanation remains to be given are distemper, fresco, oil-painting, miniature, mosaic, and the elydoric method.

The three former shall be treated of according to their order in point of time.

Fresco. Fresco is the most antient of all kinds of paints, the most speedily executed, and sometimes the most remarkable for its durability. Norden speaks of some ruins of Egyptian palaces, on the walls of which are colossal paintings, which are shewn by Winckelman to have been executed in fresco. The fragments of antient painting handed down to us by the Romans are likewise in fresco. Could this stability of colour be certain and constant, this mode of art would be preferable to all others, particularly in the decoration of palaces, temples, or other large public edifices; as it has a freshness, splendour, and vigour, unknown either to oil or water-colours. It is at the same time the most difficult of accomplishment, requiring, in the opinion of Vasari, "the greatest force of genius, boldness of execution, and readiness of pencil." The reasons for such an opinion will be seen in the following account of the mechanical process of this beautiful mode of art.

Method of painting in fresco. Before you begin to paint, it is necessary to apply two layers of stucco on the place where your work is to be executed. If you are to paint on a wall of brick, the first layer is easily applied; if of free-stone closely joined, it is necessary to make excavations in the stone, and to drive in nails or pegs of wood, in order to hold the layer together.

The first layer is made of good lime and a cement of pounded brick, or, which is better, river-sand, which latter forms a layer more uneven, and better fitted to attach the second smooth layer to its surface. The antients appear to have possessed the art of making this species of mortar superior to any now in use.

Before applying the second layer, on which you are to paint, it is requisite that the first is perfectly dry, as the lime while moist emits a pernicious effluvium.

When the first layer is perfectly dry, wet it again with water, in proportion to its dryness, that the second layer may more easily incorporate with it.

The second layer is composed of lime, slaked in the air, and exposed for a whole year, and of river-sand of an equal grain, and moderately fine. The surface of this second layer must be uniformly even. It is laid on with a trowel; and the workman is provided with a small piece of wood, to remove the large grains of sand, which, if they remained, might render the surface uneven.

To give a fine polish to this surface, a sheet of paper should be applied on it, and the trowel passed and repassed over the paper; this caution will prevent any little inequalities which might injure the effect of the painting at a distance.

The workman must not extend the layer over a greater space than the painter is able to finish in a day, as it is necessary that the ground should always be fresh and moist under his pencil; and it is on this account that the readiness of the artist's hand becomes so requisite a quality in the execution of works in fresco.

The ground being thus prepared, the painter begins his work; but as painting in fresco must be executed rapidly, and as there is not time to retouch any of the strokes of the brush with good effect, he will first have taken care to provide himself with large finished drawings in chalk, or paintings in distemper, of the same size as the work which he has to paint, so that he shall have only to copy these drawings on the wall.

These drawings are generally made on large sheets of paper pasted together, and have thence been generally termed cartoons (cartoni).

The painter traces the outlines of the figures on the plaister, by passing a steel point over them, or pricking them closely and passing very finely powdered charcoal through the pricked holes. He then proceeds to the completion of his work, having his chief tints ready prepared in separate earthen pots, and generally first trying their effect on a dry smooth tile, which quickly imbibing their moisture discovers the hue which they will have when dry on the wall.

All natural earths are good for painting in fresco. The colours are ground and tempered with water. It is to be remarked, that all the colours used in this method of painting brighten as they grow dry, excepting the pavonazzo or red varnish, the brownish red-ochre, ruth-ochre, and the blacks, particularly those that are passed through the fire.

The best colours are white, made of old lime, and white marble-dust (the proportional quantity of the latter depends on the quality of the lime, and must be found by trial, as too great a quantity of marble-dust will turn the colour black;) ultramarine-blue, the black of charcoal, yellow ochre, burnt vitriol, red earth, green of Verona, Venetian black, and burnt ochre.

Other colours, which require to be used with greater precaution, are amel, or enamel-blue, and cinnabar. Enamel-blue must be applied instantaneously, and while the lime is very moist, otherwise it will not incorporate; and if you retouch with it, you must do it an hour or more after the first application of it, in order to increase its lustre.

Cinnabar has a splendour almost beyond all other colours, but it loses it when mixed with lime. It may, however, be employed in places not exposed to the air, if proper care is used in preparing it. For this purpose, reduce a quantity of the purest cinnabar to powder, put it into an earthen vessel, and pour lime-water on it two or three times. By this process the cinnabar receives some impression from the lime-water, and you may then use it with greater safety.

The white of lime is formed by mixing lime, slaked a long time before, with good water. The lime deposits a sediment at the bottom of the vessel; when the water is poured off, this sediment is the white of lime.

Another kind of white may likewise be made from egg-shells, pounded, in great quantities, and boiled in water, together with quick-lime, and afterwards put into a strainer and washed repeatedly with spring water.

The shells must be again pounded until the water employed for that purpose becomes pure and limpid; and when the shells are completely reduced to powder, they are ground in water, made up in small pieces, and dried in the sun.

The effect of this colour must be ascertained by experiment.

Ochres of all kinds make good colours for fresco, being previously burnt in iron boxes.

Naples yellow is dangerous to be used, when the painting is much exposed to the air.

Blacks, from charcoal, peach-stones, and vine-twigs, are good; that extracted from bones is of no value.

There is another black used by the Italians, which they call fescia da botta. It is made of the lees of burnt wine.

Roman vitriol gathered at the furnaces, and called burnt vitriol, being afterwards ground in spirits of wine, resists the air extremely well. There is also a red extract from this preparation, somewhat like that of lac. This colour is a good preparatory for the layers where cinnabar is afterwards to be used; draperies painted with these two colours are as bright as fine lac used with oil.

Ultramarine never changes, and seems to communicate its permanent quality to the colours with which it is mixed.

Distemper. In addition to what has been said of this method of painting under its proper article, the following particulars are worthy of notice.

Until the discovery of oil-painting, the methods most generally adopted by all Italian painters were those of distemper and fresco.

In distemper, when they painted on boards, they often pasted over the boards a piece of fine cloth, to prevent them from parting; they then laid on a layer of white; after which, having tempered their colours with water and paste (or rather with water and yolks of eggs beat together with little fig-tree branches, the milk of which mixed with the eggs), they painted their pictures with this mixture.

All colours are proper for distemper, except the white of lime, which is used in fresco only.

Azure and ultramarine must be used with a paste made of glove-skin, or parchment, as they will turn green when mixed with yolks of eggs.

If the work is on walls, care must be taken that they are quite dry. The painter must even lay on two layers of hot paste before he applies the colours, which, if he pleases, he may also temper with paste, the composition of eggs and fig-tree branches being only retouching, and the paste rendering the work more durable. When used, it must be kept hot by fire. This paste, as has been said, is made of glove-skin or parchment.

All their designs for tapestry were made on paper, in the same manner as has been mentioned in the account of the cartoons used for fresco-painting.

When a painter in distemper would work on cloth, he must chuse that which is very old and smooth; then press pounded plaister with glove-skin paste, and lay it over the cloth; when dry, add another layer of the same paste.

All the colours are pounded with water, and as the painter wants them for his work, he tempers each with paste-water; or if he will only make use of yolks of eggs, he takes of water one glass, to which he adds an equal quantity of vinegar, the yolk, white, and shell of an egg, and some ends of fig-tree branches cut into small pieces, and beats them all well together in an earthen pan.

If he wishes to varnish his picture when finished, he must rub it with the white of an egg well beaten, and then put on a single coat of varnish.

Oil painting. The principal advantage of oil-painting over other methods consists in the colours drying less speedily, so that it allows the painter to finish, smooth, and retouch his works, with greater care and precision. The colours also being more blended together, produce more agreeable gradations, and a more delicate effect.

The antients are said (see the historical part of this article) to have been ignorant of the secret of painting in oil, which is only the grinding the usual colours in several kinds of oil, as poppy-oil, nut-oil, and linseed-oil. This method was likewise unknown to the first masters of the modern Italian schools, and is generally thought to have been discovered in the 14th century. It was first used on board or pannel, afterwards on plates of copper, and on linen cloth. Whichever of these materials is used for the purpose of painting on, it is requisite that a ground of colour is previously laid, which is called the priming; or else that they are covered with a layer of size, or other glutinous substance, to prevent the oil from penetrating, and being wholly absorbed during the painting of the picture. These preparations are familiarly known to all colourmen.

In some of the pictures of Titian and Paolo Veronese, there is reason to believe that they laid their ground with water-colours, and painted over it with oil, which contributed much to the vivacity and freshness of their works, by the ground gradually imbibing so much of the oil as may be requisite to preserve the brightness of the natural colours.

As the superior beauty of oil-painting depends on the vividness and delicacy of durable tints, we shall present the student with the best rules drawn from a careful study of the works of Vandyck and Rembrandt, two of the most remarkable colourists in different styles. These rules are arranged in so easy a method, that the student may be led, step by step, through all the difficulties of this nice and pleasing progress.

We shall first treat of the painting of flesh, next of draperies, then of the back-ground, and lastly of landscapes.

OF PAINTING FLESH.

Principal colours from which all the tints of the flesh are made, and their qualities in painting.

Flake-white is the best white known to us. This colour should be ground with the finest poppy-oil that can be procured. It is often found to turn yellow, on account of the oil, generally sold by that name, not being really drawn from poppies.

White comes forward to the eye with yellows and reds, but retires with blues and greens. It is the nature of all whites to sink into whatever ground they are laid on, therefore they should be laid on white grounds.

Ivory-black is the best black: it is a colour which mixes kindly with all the others. It is the true shade for blue; and when mixed with a little Indian red, it is the best general shadow-colour that can be used. It is generally ground with linseed-oil, and used with drying oil.

Black is a cold, retiring colour.

Ultramarine is the finest blue in the world: it is a tender retiring colour, and never glares, and is a beautiful glazing colour. It is used with poppy-oil.

Prussian-blue is a very fine blue, and a kind-working colour: it is ground with linseed-oil, though nut-oil is more proper. It should never be used in the flesh, but in green tints and the eyes.

Light-ochre is a good mixing colour, and of great use in the flesh: it is usually ground with linseed-oil, but nut-oil is better. All yellows are strengthened with red, and weakened with blues and greens.

Light-red is nothing but fine light ochre burnt. This and white, in mixing, produce a most perfect flesh-colour. It is a beautiful, clean colour; but too strong for the white, and therefore will grow darker. It should be ground and used with nut-oil.

No vermilion but what is made of the true native cinnabar should be used. It will not glaze; but is a fine colour when it is glazed. It is ground with linseed-oil, and should be used with drying oil.

Carmine is the most beautiful crimson: it is a middle colour, between lake and vermilion; is a fine-working colour, and glazes well It should be ground with nut-oil, and used with drying oil.

Lake is a tender deep red, but of no strong body; therefore it should be strengthened with Indian red. It is the best glazing colour that can be used. It is ground with linseed-oil, and used with drying oil.

Indian red is a strong pleasant-working colour, but will not glaze well; and when mixed with white, falls a little into lead: it is ground and used as the lake.

Brown pink is a fine glazing colour, but of no strong body. In the flesh it should never join or mix with the lights, because this colour and white antipathize, and mix of a warm dirty hue; for which reason their joinings should be blended with a cold middle tint. In glazing of shadows it should be laid before the other colours that are to enrich it: it is one of the finishing colours, and therefore should never be used in the first painting. It is strengthened with burnt umber, and weakened with terraverte; ground with linseed-oil, and used with drying oil.

Burnt umber is a fine warm brown, and a good working strong colour: it is of great use in the hair, and mixes finely with the warm shade.

Principal tints, composed from the foregoing principal colours, and necessary for painting flesh.

Light red tint is made of light red and white: it is the best-conditioned of all colours, for the general ground of the flesh. With this colour and the shade tint, you should make out all the flesh, like claro-obscuro, or mezzotinto. Remember, that this colour will grow darker, because it is in its nature too strong for the white; therefore you should improve it, by mixing vermilion and white with it, in proportion to the fairness of the complexion.

Vermilion tint is only vermilion and white mixed to a middle tint: it is the most brilliant light red that can be. It agrees best with the white, light red, and yellow tints.

Carmine tint is carmine and white only, mixed to a middle tint; it is, of all colours, the most beautiful red for the cheeks and lips: it is one of the finishing colours, and should never be used in the first painting, but laid upon the finishing colours without mixing.

Rose tint is made of the red shade and white, mixed to a middle degree, or lighter: it is one of the cleanest and most delicate tints that can be used in the flesh, for clearing up the heavy dirty colours, and in changing will sympathize and mix kindly.

Yellow tint is often made of Naples yellow and white; but it is as well to use light ochre and white, which is a good working colour. The ochre is too strong for the white; therefore you should make a little allowance in using it. It follows, the light red tints and yellows should always be laid before, the blues. If you lay too much of it, you may recover the ground it was laid on with the light red tints.

Blue tint is made of ultramarine and white, mixed to a lightish azure: it is a pleasant-working colour; with it you should blend the gradations. It follows the yellows, and with them it makes the greens; and with the reds it produces the purples. No colour is so proper for blending down, or softening the lights into keeping.

Lead tint is made of ivory-black and fine white, mixed to a middle degree: it is a retiring colour, and therefore is of great use in the gradations, and in the eyes.

Green tint is made of Prussian blue, light ochre, and white. This colour will dirty the lights, and should be laid sparingly in the middle tints. It is of most use in the red shadows, where they are too strong.

Shade tint is made of lake, Indian red, black, and white, mixed to a beautiful murrey colour, of a middle tint. This is the best mixture for the general ground of shadows. It mixes well with the lights, and produces a pleasant clean colour, a little inclined to the reddish pearl. As all the four colours of its composition are of a friendly sympathizing nature, so consequently this will be the same, and therefore may be easily changed by the addition of any other colours.

Red shade is nothing but lake and a very little Indian red. It is an excellent working colour, and a good glazer: it strengthens the shadows on the shade tint, and receives, when it is wet, the green and blue tints agreeably. It is a good ground for all dark shadows.

Warm shade is made of lake and brown pink, mixed to a middle degree. It is a fine colour for strengthening the shadows on the shade tint, when they are wet or dry. Take care that it does not touch the lights, because they mix of a dirty colour, and therefore should be softened off with a tender cold tint.

Dark shade is made of ivory-black and a little Indian red only. This colour mixes very kindly with the red shade, and blends agreeably with the middle tints in the dead colouring. It is excellent for glazing the eyebrows and the darkest shadows.

Process. The process of oil-painting, particularly in the colouring of flesh and in landscape, is to be divided into three stages, or paintings.

The colours and tints necessary for the first and second stages of painting flesh, are; 1. flake, or fine white; 2. light ochre and its tints; 3. light red and its two tints; 4. vermilion and its tint; 5. a tint composed of lake, vermilion, and white; 6. rose tint; 7. blue tint; 8. lead tint; 9. green tint; 10. half-shade tint, made of Indian red and white; 11. shade tint; 12. red shades; 13. warm shade.

The finishing pallet for a complexion requires five more, viz. 1. carmine and its tint; 2. lake; 3. brown pink; 4. ivory-black; 5. Prussian blue.

First stage, or dead-colouring of flesh.

The first lay of colours consists of two parts; the one is the work of the shadows only, and the other that of the lights.

The work of the shadows is, to make out all the drawing very correctly with the shade tint, in the same manner as if it was to be done with this colour only; and remember to drive or lay the colour sparingly. The lights should be all laid in with the light red tint, in different degrees, as we see them in nature. These two colours united, produce a clean, tender, middle tint. In uniting the lights and shades, you should use a long softener, about the size of a large swan-quill, which will help to bring the work into character, and leave the colouring more delicate; then go over the darkest shadows with the red or warm shade, which will finish the first lay.

The warm shade being laid on the shade tint, improves it to a warmer hue; but if laid instead of the shade tints, it will dirty and spoil the colours it mixes with; and if the red shade is laid first, instead of the shade tint, the shadows would then appear too red; therefore, notwithstanding these two colours are the best that can be for the shadows, yet they are too strong to be laid alone, which is a proof of the great use and merit of the shade tint. Here we may observe that the shade and light-red tints are so friendly in their nature, that even in continually altering and changing, they always produce a clean colour of a pearly hue.

Next. In order to finish the first painting, improve the reds and yellows to the complexion, and after them the blues; observing, that the blues on the reds make the purple, and on the yellows produce the green. The same method is to be understood of the shadows; but be sure to leave them clean, and not too dark; therefore allowance should be made in the grounds with the light red, because glazing them will make them darker. When the cloth is of a dark, or bad colour, there must be a strong body of colour laid all over the shadows, such as will not sink into the ground, but appear warm, and a little lighter than the life, so that it may be of the same forwardness to finish as if it had been a light ground; therefore the business of dead-colouring is, that you leave it always in the same order for finishing, though the colour of the cloth is quite the reverse.

The grounds of shadows, in what we call the dead-colouring, should be such as will support the character of the finishing colours; which ground must be clean, and a little lighter than the finishing colours, because the finishing of the shadows is glazing; and no other method than glazing can leave such brilliancy and beauty as they ought to have. If you begin the first painting with glazing, it will stare, and be of no use; and the solid colours which are laid on it, will look heavy and dull; therefore, all shadows and colours that are to be glazed, should be done with colours of a clean solid body, because the glazing is more lasting, and has the best effect, on such colours. Remember to leave no roughness, that is, none such as will appear rough, and interrupt or hurt the character of the finishing colours; which, by examining the work, whilst it is wet, with a soft tool, or when it is dry with a knife, may be avoided, as it will easily take off the knots and roughest parts.

The light red and white improved is superior to all other colours for the first lay or ground; which should be always done with a full pencil of a stiff colour, made brighter than the light, because it will sink a little in drying. The greater the body and quantity of colour, and the stiffer it is laid, the less it will sink. Every colour in drying will sink, and partake, in proportion to its body, of the colour it is laid on; therefore, all the lights of the flesh, if not laid on a light ground, must consequently change a little from the life, if there is not allowance made. The shade tint for the shadows should fall into the rose tint, as the complexion grows delicate; all which should be lightly united, with a soft long pointed hog-tool, to the lights, making out the whole like mezzotinto. The great masters very seldom softened or sweetened the colours; but in uniting the first lay, they were very careful in preserving the brightness of their colours, and therefore did not work them below the complexion: for to force or keep up a brilliancy in the grounds, can only be done with the whites, reds, and yellows, which method will make up for the deficiency of the white grounds; therefore, the first painting should be left bright and bold, and the less the colours are broken the better. You should forbear using any colours that will produce them, and be contented to add what is wanting in the next painting; where, if you fail, a clean rag will restore the first ground.

Second painting, or second stage.

The second painting begins with laying on the least quantity, that can be, of poppy-oil; then wipe it almost all off, with a dry piece of a silk handkerchief.

The second painting is also divided into two parts: one, the first lay of the second painting; which is scumbling the lights, and glazing the shadows; the other, finishing the complexion with the virgin tints, and improving, as far as you can, without daubing.

First. Scumbling is going over the lights, where they are to be changed, with the light red tints, or some other of their own colours, such as will always clear and improve the complexion, with short stiff pencils; but such parts only as require it, otherwise the beauty of the first painting will be spoiled.

The light red tint improved is the best colour for scumbling, and improving the complexion in general. Where the shadows and drawing are to be corrected, you should do it with the shade tint, by driving the colour very stiff and bare, that you may the easier retouch and change it with the finishing tints. Some parts of the shadows should be glazed with some of the transparent shadow-colours, such as will improve and come very near to the life; but be sure not to lay on too much of it, for fear of losing the hue of the first painting, the ground of which should always appear through the glazing. Be very careful in uniting the lights and shades, that they do not mix dead and mealy; for the more the lights mix with the shades, the more mealy those shades will appear. Thus far the complexion is prepared and improved, in order to receive the virgin tints.

Second. Go over the complexion with the virgin tints. These are the colours which improve the colouring to the greatest perfection, both in the lights and shadows.

This should be done in the same manner as you laid them in the second part of the first painting; that is, with the reds, yellows, and blues, blending them with delicate light touches of the tender middle tints, without softening. Leave the tints and their grounds clean and distinct, and be content to leave off whilst the work is safe and unsullied, leaving what is farther required for the next sitting; for in attempting the finishing touches before the other is dry, you will lose the spirit and drawing, and your colours will become of a dirty hue.

Third painting, or finishing.

It is to be supposed, the complexion now wants very little more than a few light touches; therefore there will be no occasion for oiling.

Begin with correcting all the glazing; first, where the glazing serves as a ground or under part; then determine what should be done next, before you do it, so that you may be able to make the alteration on the part with one stroke of the pencil. By this method you preserve both the glazing and the tints; but if it happens that you cannot lay such a variety of tints and finishing colours as you intended, it is much better to leave off while the work is safe and in good order; because those few touches, which would endanger the beauty of the colouring, may easily be done, if you have patience to stay till the colours are dry; and then, without oiling, add those finishings with free light strokes of the pencil.

Rembrandt touched up his best pictures a great many times, letting them dry between. It was this method which gave them their surprising force and spirit. It is much easier to soften the over-strong tints when they are dry, than when they are wet; because you may add the very colours that are wanting, without endangeaing the dry work. If any of the colours of the pallet want to be a little changed to the life, when you are painting, it is much better to do it with the knife on the pallet than with the pencil, because the knife will mix and leave it in good order for the pencil.

Of painting draperies.

In order to shew the nature and different degrees of colours of tints used in painting draperies, we must first determine how many divisions are absolutely necessary to make the first lay of colours, and after that the reflections and finishing tints.

The right method of painting draperies in general is to make out the whole, or the first lay, with three colours only, viz. the lights, middle tint, and shade tint.

Observe that the lights should rather incline to a warmish hue; and the middle tint should be made of friendly-working colours, such as will always mix of a clean, tender, coldish hue. The shade tint should be made of the same colours as the middle tint, only with less light; therefore this tint will also mix of a tender clean colour. The beauty and character of the folds, the shape, attitude, and principal lights and shades, are all to be considered, and made with these three colours only; which should be done to your satisfaction, before you add any of the reflects, or finishing tints.

The reflections of draperies and satins are generally productions of their own, and are always lighter than the shadows on which they are found; and being produced by light, will consequently have a light warm colour, mixed with the local colour that receives them. Here it will be necessary to notice the general method of managing the colours of the first lay, and those of the reflections and finishing tints.

In the first lay, the high lights should be laid with plenty of stiff colours, and then shaped and softened into character with the middle tint very correctly. Where the gradations of the lights are slow, as in the large parts, it will be proper to lay the middle tint first at their extremities, with a tool that will drive the colour, and leave it sparingly; because the lights will mix and lie the better upon it. Next make out all the parts of the shadows with the tint driven bare. After this comes the middle tint, for the several lights and gradations; which should be very nicely wrought up, to character without touching any of the high lights which finish the first lay.

The reflects and finishing tints are in general the antipathies of the first lays: they will, without great care, dirty the colours on which they are laid; and therefore should be laid with a delicate light touch, without softening. If it is overdone, endeavour to recover it with the colour of the part on which it was laid: this may be done directly, or when it is dry. Whether the reflects proceed from the same colour, or any other, the method of using them is the same.

Before we proceed to the particular colours, it will be proper to make some observations on their grounds.

It often happens, that the colour of the cloth is very improper for the ground of the drapery; and when it is so, you should change it with those colours which are most proper to improve and support the finishing colours. This method of dead-colouring must consequently preserve them in the greatest lustre. In dead-colouring, you should lay the lights and shades in a manner so as only to shew a faint idea of them, with regard to the shape and roundings of the figure. If you have a design to work from, then it will be proper to make all the large and principal parts in their places: which should always be done with a colour that is clean, and lighter than the intended drapery, though in general of the same hue; and let the shadows be no darker than a middle tint. These should be mixed and broke in a tender manner, and then softened with a large tool, so that nothing rough and uneven is left to interrupt or hurt the character of the finishing colours.

White satin. All whites should be painted on white grounds, laid with a good body of colour, because this colour sinks more into the ground than any other.

There are four degrees of colours in the first lay, to white satin. The first is the fine white for the lights; the second is the first tint, which is made of fine white and a little ivory-black, mixed to an exact middle degree between the white and the middle tint. This colour follows the white; and it is with this you should shape the lights into character before you lay on any other: and take care that this first tint appears distinctly between the white and the middle tint, otherwise the beauty and the character of the satin will be spoiled.

The middle tint should be made of white, black, and a little Indian red. These three colours are very friendly, and mix to a beautiful clear colour of a pearly hue, which has the true brightness and warmth of the general hue of the satin. Remember to allow for the red hue changing a little to the lead. If there is occasion to make any part in the middle tint lighter, do it with the first tint only. This colour should also be laid sparingly before the white, in all the little lights that happen in the middle tints and shadows; on which you should lay the white with one light touch, and be sure not to cover all the parts that were made with the first tint; if you do, it will spoil the character, and look like a spot, for want of the softening edge or border, which must be between the white and the middle tint. The shade tint should be made of the same colour as the middle tint, but with less white, so that it is dark enough for the shadows in general; with which make out all the parts of the shadows nicely to character, which is the work of the first lay.

Next follow the reflects and finishing tints.

Brown ochre, mixed with the colour of the light, is the most useful colour in general for all reflects in draperies, that are produced from their own colours. All accidental reflexes are made with the colour of the parts from which they are produced, and the local colours that receive them. There are but two reflecting tints wanted for draperies in general: one should be lighter than the middle tint, the other darker. These colours may be a little changed on the pallet with the first and middle tints, as occasion requires, or lightly broken on the part that receives them; but this last method is not so safe as the other. The tint sufficient for blending the dark shadows to the mellow tender hue, is made with the shade tint and a little brown ochre, which should be laid on very sparingly, with soft light touches, for fear of making them dull and heavy; if it is overdone, recover it with the colour it was laid upon.

We often see a little blue used in the first tint of white satin. Van Haecken, who was the best drapery-painter in England, did so; and sometimes, instead of the blue, he used blue-black, till he found it to be a pernicious colour, and was therefore obliged to use blue; because his middle tint, which was only of black and white, was so very cold, that no other colour but blue would make a colder tint; yet he managed these cold colours, in all the lights and middle tints, so agreeably, and so light and easy was his touch, that we may learn something from him.

Blue satins. Blue satin is made of Prussian blue and fine white.

The best ground for blue is, white for the lights, and black and white for the shadows.

The first lay of colours for blue is divided into three degrees or tints. First make the middle tint of a beautiful azure; then mix the colour for the light about a middle degree, between that and white. Make the shade tint dark enough for the shadows in general. All the broad lights should be laid with plenty of colour, and shaped to character with the middle tint, before you lay on any other colours. Remember, the less colours are mixed, the better they will appear and stand; for the lights of blue should be managed with as much care as those of white satin. Next follow with the rest of the middle tint, and then make out all the shadows. The more you drive the shade tint, the better it will receive the reflects and finishing tints. The shadows should be strengthened and blended with ivory-black, and some of their own colour, which will mix with them into a tender mellow hue.

The reflects are made as those of white satin, that is, with ochre, and some of the lights; which should be perfectly done, as you intend them, at once painting. The shadows, when dry, may be a little improved, if there is occasion to alter them, with the colours they were made with. The Prussian proper to be used, is that which looks of the most beautiful azure before it is ground; and the sooner it is used after it is ground, the better it will work and appear.

Velvet may be painted at once. The method is, to make out the first lay with the middle tint and shade tint; on which lay the high lights, with light touches, and finish the shadows in the same manner as those of satin: but the nearest imitation of velvet is done by glazing; the method of which is, to prepare a ground, or dead-colouring, with such colours as will, when dry, bear out and support the glazing colour in its highest perfection. The nature of the glazing colour is to be of a fine transparent quality, and used simply with oil only, so that whatever ground it is laid on, the whole may appear distinctly through it. The best ground for blue is made with white and ivory-black: the white is for the high lights, which, with the middle tint and shade tint, makes out the first lay like mezzotinto. Remember to make the middle tint lighter in proportion to the glazing, because that will make it darker. It is often necessary to cover all but the high lights, with a thin glazing, laid in less quantity than if it was to be done once only. If any of it touches the lights, wipe it off with a clean rag. The very high lights should be improved, and made of a fine white, and left to dry. The glazing colour is Prussian, ground very fine with nut oil; and should be laid with a large stiffish tool. It is on the last glazing we should strengthen and finish the shadows.

The greatest fault in the colouring of draperies is the painting the shadows with strong glaring colours, which destroy the beauty of the lights. This is not only the reverse of art, but of nature, whose beauty always diminishes in proportion with the lights. For this reason, take care to blend and soften the shadows with such friendly colours as will agree with their local character and obscurity. Here observe, that glazing the middle tint, which is made of black and white, will not produce a colour so blue as if it had been prepared with Prussian and white; yet this colour will preserve the beauty of the lights in the highest perfection, by reason of its tender obscure hue, when the blueness of the other would only diminish them. This method of glazing the blue is the general rule for all glazing.

When glazing blue, the lights may be glazed with ultramarine, though all the other parts are done with Prussian. This method saves a great quantity of that valuable colour, and answers the purpose as well as if it had been done with ultramarine.

Though this general method of painting satins is to make the first lay of colours with three degrees, or tints, yet you should understand, in using them, that they produce two more; for the mixing of two different colours together on the cloth will make another of a middle tint between them; so it is with the lights and middle tints, and with the middle tint and shade tint: the first answers to the first tint in white satin, and the last will consequently be a sort of gradating, or half shade.

If the lights and middle tint mix to a beautiful clean colour, of a middle hue between both, there will be no occasion for a colour to go between them, as in blue satin: but if in mixing they produce a tint inclined to a dirty warm hue, then another of a sympathizing nature should be laid between them, in order to preserve the beauty of the lights, as the first tint in the white satin; for if it was not so, the red in the middle tint would certainly dirty and spoil the white.

It is highly necessary to understand these principles of the first lay of colours, in order to have a perfect knowledge of the general rule of colouring.

Scarlet and crimson. A light yellow red, made of light ochre, light red, and white, is the proper ground for scarlet; the shadows are Indian red, and in the darkest parts mixed with a very light black.

The second painting should be a little lighter than you intend the finishing colour, that is, in proportion to the glazing, which will make it darker.

The high lights are vermilion and white for satin and velvet, and vermilion for cloth. The middle tint is vermilion, with a very little lake or Indian red; the shade tint is made with Indian red and lake, with the addition of a little black in the darkest shadows. The difference between scarlet and crimson is, that the high lights of crimson are whiter, and the middle tint is made darker. Their reflects are made with light red and vermilion. The high light should be laid and managed in the same manner as those of the blue, for fear of dirting them; and sometimes they require to be touched over the second time before we glaze them. The more the colours of the second painting are drove, the easier and better they may be managed to character; but the high lights should have a good body of colour, and be left with a delicate light touch. After it is well dry, finish with glazing the whole with fine lake, and improve the reflects and shadows. Remember that the scarlet requires but a very thin glazing; and it is better to glaze the crimson twice over, than lay too much at once painting.

Pink colour. There are two different methods of painting a pink colour; one is by glazing, the other is done with a body of colours at one painting. The same grounds do for both: which should be a whitish colour, inclining to a yellow, for the lights; and Indian red, lake, and white, for the shadows.

The second painting, for the glazing method, is done with the same colours, and a little vermilion and white for the high lights. When it is dry, glaze it with fine lake, and then break and soften the colours into harmony directly.

The other method is to make the high lights with carmine and white; the middle tint with lake, white, and a little carmine; and the shadows with lake and Indian red, with a little vermilion for the reflections. But remember, the shadows will require to be broken with some tender obscure tint.

Yellow. The ground for yellow should be a yellowish white for the lights, and a mixture of the ochres for the shadows.

There are the same number of tints in the yellow, as there are in the white satin, and the method of using them is the very same. The lights are made with king's yellow, ground with clean good drying oil. The first tint is light ochre, changed with a little of the pearl tint, made with the dark shade and white, which should be laid and managed as the first tint in white satin. The middle tint is a mixture of the light and brown ochre, softened with the pearl tint. The shade tint is made with brown pink and brown ochre; these belong to the first lay.

The reflects are light ochre, and sometimes in the warmest parts mixed with a little light red. The shadows are strengthened with brown pink and burnt umber.

Green. The proper ground for green is a light yellow green, which is made of light ochre, a little white, and Prussian blue, for the lights, and the ochre, brown pink, and Prussian, for the shadows.

The finest green for draperies is made of king's yellow, Prussian blue, and brown pink. The high lights are king's yellow, and a very little Prussian; the middle tint should have more Prussian; and the shadow tint is made with some of the middle tint, brown pink, and more Prussian; but the darkest shadows are brown pink and a little Prussian. The lights and middle tint should be managed in the same manner as those of the blues. The shadow tint should be kept entirely from the lights, because the brown pink that is in it will, in mixing, dirty them, as the black does those of the blues. Remember to allow for their drying a little darker; and that the king's yellow must be ground with good drying oil; for the longer it is drying, the more it will change and grow darker; and the sooner it is used, the better it will stand. It is proper to have two sorts of king's yellow, one to be very light, for the high lights of velvet.

Changeable colours. Changeable colours are made with four principal tints, viz. the high lights, middle tint, shade tint, and reflecting tint.

The greatest art lies in finding the exact colour of the middle tint, because it has more of the general hue of the silk than any of the others. The shade tint is of the same hue with the middle tint, though it is dark enough for the shadows. The high lights, though often very different from the middle tint, should be of friendly-working colour, that will, in mixing with it, produce a tint of a clean hue.

The method of painting silks is to make out the folds with the shade tint, and then fill them up in the lights with the middle tint. This first lay should be done to your satisfaction before you add any other colours; and the stiffer the middle tint is used, the better the high lights may be laid upon it. The reflecting tint falls generally upon the gradating half-shades, and should be laid with tender touches sparingly, for fear of spoiling the first lay.

This method of painting answers for all coloured silks, as well as changeable, with this difference only; that the plain colours require not so much art in matching the tints, as the changeable do. The last part of the work is the finishing and strengthening the shadows with an obscure tint, a little inclining to a mellowish hue; such as will not catch the eye, and interrupt the beauty of the lights.

Black. The best ground for black is light red for the lights, and Indian red and a little black for the shadows.

The finishing colours are, for the lights, black, white, and a little lake. The middle tint has less white, and more lake and black; the shade tint is made of an equal quantity of lake and brown pink, with a very little black.

The method of painting black is very different from that of other colours; for as in these the principal thing is to leave their lights clear and brilliant; so in black, it is to keep the shadows clear and transparent. Therefore begin with the shade tint, and glaze over all the shadows with it. Next lay in the darkest shadows with black, and a little of the shade tint, very correctly. After that, fill up the whole breadth of lights with the middle tint only. All which should be done exactly to the character of the satin, velvet, cloth, &c. &c. and then finish with the high lights.

Here observe, the ground, being red, will bear out and support the reds, which are used in the finishing colours. The lake in the lights takes off the cold hue, and gives it a more beautiful colour. If the shade tint was of any other colour than a transparent warm hue, the shadows would consequently be black and heavy; because no other colours can preserve the warm brilliancy which is wanting in the shadows of the black, like lake and brown pink. Black is of a cold heavy nature, and always too strong for any other colour; therefore you should make an allowance in using it. There will be a few reflects in satin, which should be added as those of other colours; but they should be made of strong colours, such as burnt umber, or brown ochre, mixed with a little shade tint.

Though the grounds mentioned for the draperies are absolutely necessary for the principal and nearest figures in a picture, such as a single portrait, or the like; yet for figures which are placed behind the principal or front figures, their grounds should always be fainter in proportion to their local finishing colours.

Linen. The colours used in linen are the same as those in white satin, except the first tint, which is made of white and ultramarine ashes, instead of the black, and mixed to a very light bluish tint.

In the dead-colouring, take particular care that the grounds are laid very white and broad in the lights. The shadows are made with black, white, and a little Indian red, like the middle tint of white satin. These should be left very light and clean, in order to support the finishing colours.

The second painting begins with glazing all the lights, with a stiff pencil and fine white only, driven bare, without using any oil. The shadows may be scumbled with poppy-oil, and some of the colour they were made of. This is the first lay, on which you are to follow with the finishing colours directly. The middle tint of white satin is the best colour for the general hue of the shadows. With this and white, in different degrees, make out all the parts to character, with free light touches, without softening; then, with a large long-pointed pencil and fine white, lay the high lights very nicely with one stroke. After this comes the fine light bluish tint, which should be mixed light, and laid in the tender gradations, very sparingly and lightly, without filling them up.

Remember, the first lay should be left clear and distinct; the more it appears, the better. It is the overmixing and joining all the colours together, which spoils the beauty of the character; therefore it is better to let it dry before we add the reflects and finishing tints.

The method of letting the beautiful clear colour dry, before you add the warm reflects, and harmonizing tints, prevents them from mixing and dirting each other.

The principal blending colours used in the reflects are the yellow tint, green tint, and rose tint; which last is made of lake, Indian red, and white. Glazing the pearl and lead-colour with white, though it seems to answer our purpose at the time when it is done, will certainly sink and be lost in the grounds on which it is laid; therefore you should make the dead-colouring as white as you intend the finishing colours, by reason they will sink a little in proportion to the colour of the cloth, which the glazing with pure white only will recover.

Of painting back grounds.

The principal colours that are necessary for painting of back-grounds, as walls, buildings, or the like, are white, black, Indian red, light and brown ochre, Prussian, and burnt umber; from which the eight principal tints are made, as follows:

1. Pearl is made of black, white, and a little Indian red.
2. Lead, of black and white, mixed to a dark lead-colour.
3. Yellow, of a brown ochre and white.
4. Olive, of light ochre, Prussian, and white.
5. Flesh, of Indian red and white, mixed to a middle tint.
6. Murrey, of Indian red, white, and a little black, mixed to a kind of purple, of a middle tint.
7. Stone, of white, umber, black, and Indian red.
8. Dark shade, of black and Indian red only.

Here the lead tint serves for the blues, the flesh tint mixes agreeably with the lead, and the murrey is a very good blending colour, and of great use where the olive is too strong; the umber, white, and dark shade, will produce a fine variety of stone colours; the dark shade and umber, used plentifully with drying oil, make an excellent warm shadow-colour. All the colours should be laid with drying oil only, because they mix and set the better with the softener.

Where the marks of the trowel are so strong in the priming of the cloth, that one body of colours will not be sufficient to conceal it, lay a colour to prevent it, which should be dry before you begin with those parts you expect to finish at once painting.

Process. The process of painting back-ground is divided into two parts in stages; the first is the work of the first lay, the second that of the finishing tints.

Begin the first lay from the shadowed side of the head, and paint the lights first; from them go into the gradations and shadows, which should be done with a stiffish tool, very sparingly, with the dark shade and white, a little changed with the colours that will give it more of the required hue, but very near in regard to tone and strength, leaving them like mezzotinto.

The dark and warm shadows should be laid before the colours that join them. This do with the dark shade and umber, driven with drying oil. If those colours were laid on first, they would spoil the transparency, which is their greatest beauty. The more the first lay is driven, the easier and better you may change it with the finishing tints, therefore you may lay them with the greater body.

The second part is to follow directly, whilst the first lay is wet, with those tints that are the most proper to harmonize and finish with.

Begin with the lights first, and remember, as you heighten and finish them, to do it with warmer colours; and let those be accompanied with fine tender cold tints. The lightest parts of the ground should be painted with a variety of light warm clear colours, which vanish and lose their strength imperceptibly in their gradations. Take care that you do not cover too much of the first lay, but consider it as the principal colour.

From the lights, go to the gradations and shadows; for when the lights are well adapted to produce and support the figure, it is easy to fall from them into whatever kind of shadows you find most proper; then soften and blend the whole with a long large hog-tool; which, with the strength and body of the drying oil, will melt and sweeten altogether, in such a manner, as will seem surprisingly finished. Remember the tints will sink, and lose a little of their strength and beauty in drying. All grounds, as walls, &c. should be finished at once painting; but if they want to be changed, glaze them with a little of the dark shade and drying oil, driven very bare; on which, with a few light touches of the colour that is wanting, you may improve their hue. The dark shadows may also be strengthened and improved by glazing, which should be done after the figures are nearly finished, for fear of making them too strong.

Rembrandt's grounds are rather brighter in the lights, and have more variety of tints than any other painter's; for he had observed, that those tints diminish in proportion with the lights; therefore his shadows have but a faint appearance of tints. He understood the gradations in perfection, by mixing and breaking the first lay of colours so artfully, that they deceive in regard to their real strength.

Vandyck's general method was, to break the colours of the ground with those of the drapery. This will certainly produce harmony.

Fresnoy says, let the field or ground of the picture be pleasant, free, transient, light, and well united with colours which are of a friendly nature to each other; and of such a mixture as that there may be something in it of every colour that composes your work, as it were the contents of your pallet.

Curtains should be dead-coloured when we paint the ground; and should be done with clean colours, of a near hue to the intended curtain, such as will support the finishing colours; do it with a tender sort of keeping, and near in regard to their tone in the lights, but much softer in the shadows; all which should be mixed and broken with the colours of the ground. It will often happen, that we cannot make the folds the first painting; we should then leave the masses of light and shadow, in regard to the keeping of the picture, broad and well united together, such as may seem easy to finish on. The colours of the landscape, in back-grounds, should be broke and softened also with those of the parts which join them. This method will make all the parts of the ground, as it were, of one piece.

The sky should be broke with the lead and the flesh-tints. The murrey tint is of great use in the grounds of distant objects; and the umber and dark shades in the near grounds. The greens should be more beautiful than you intend them, because they will fade and grow darker. After all is painted, go over the whole very lightly with the softener, as you did the grounds, which will make it look agreeably finished.

Of painting landscapes.

The principal colours used in landscapes are; 1. flake white; 2. white lead, or common white; 3. fine light ochre; 4. brown ochre; 5. brown pink; 6. burnt umber; 7. ivory black; 8. Prussian blue; 9. ultramarine; 10. terreverte; 11. lake; 12. Indian red; 13. vermilion, or native cinnabar; 14. king's yellow.

The principal tints are, 1. Light ochre and white; 2. Light ochre, Prussian blue, and white; 3. Light ochre, and Prussian blue; 4. The same darker; 5. Terreverte and Prussian blue; 6. Brown pink and Prussian blue; 7. Brown pink and brown ochre; 8. Brown pink, ochre, and Prussian blue; 9. Indian red and white; 10. Ivory-black, Indian red, and lake.

The colours necessary for dead-colouring, are: common white, light ochre, brown ochre, burnt umber, Indian red, ivory-black, and Prussian blue.

The principal colours and tints for painting the sky, are, fine white, ultramarine, Prussian blue, light ochre, vermilion, lake, and Indian red.

The tints are, a fine azure, lighter azure, light ochre and white, vermilion and white; and a tint made of white, a little vermilion, and some of the light azure, at your discretion.

Process. Sketch or rub in your design faintly, with burnt umber used with drying oil, and a little oil of turpentine; leaving the colour of the cloth for the lights. Remember, in doing this, to leave no part of the shadows so dark as you intend the first lay or dead-colouring, which also is to be lighter than the finishing colours. Though the foliage of the trees is only rubbed in faintly, yet the trunks and bodies should be in their proper shapes, with their breadths of light and shadow. All kind of buildings should be done in the same manner, leaving the colour of the cloth for their lights. The figures on the fore-ground may also be sketched in the same manner, and then left to dry.

First painting or dead-colouring.

Let the first lay, or dead-colouring, be without any bright, glaring, or strong dark colours; so that the effect is made more to receive and preserve the finishing colours, than to shew them in their first painting.

The sky should be done first, then all the distances; and so work downwards to the middle group, and from that to the fore-ground, and nearest parts. Remember, all the parts of each group, as trees, buildings, or the like, are all painted with the group they belong to.

The greatest secret in dead-colouring is, to find the two colours which serve for the ground of shadows in general, the sky excepted; and the method of using them with the lights: the first of which is the dark shade with a little lake in it; the other colour is only burnt umber. These should be a little changed to the natural hue of the objects, and then laid on with drying oil, in the same manner as we shade with Indian ink, which is a kind of glazing, and as such they should be left; otherwise they will be dark and heavy, and therefore would be entirely spoiled for the finishing glazing. Both these colours mix and sympathize agreeably with all the lights, but should be laid before them.

The sky. The sky should be laid with a good body of colours, and left with a faint resemblance of the principal clouds, more in the manner of claro obscuro than with finishing colours; the whiter it is left, the better it will bear out and support them; the distances should be made out faint and obscurely, with the dark shades, and some of their lights in different degrees, and laid so as best to find and shew their principal parts. All the grounds of the trees should be laid or rubbed in, enough only to leave an idea of their shapes and shadows faintly. The ground of their shadows must be clean, and lighter than their finishing colours.

In painting the lights, it is better to incline more to the middle tint, than to the very high lights; and observe to leave them with a sufficient body of clean colours, which will preserve the finishing colours better; all which may be done with a few tints. After this, go over the whole with a sweetener very lightly, which will soften and mix the colours agreeably for finishing.

Second painting.

Begin with the sky, and lay in all the azure, and colours of the horizon; then soften them: after that, lay in the general tint of the clouds, and finish on it with the high lights, and the other tints that are wanting, with light tender touches; then soften the whole with a sweetener, very lighty. The finishing of the sky should be done all at one painting, because the tender character of the clouds will not do so well as when the whole is wet. Observe, that the stiffer the azure and colours of the horizon are laid, the better the clouds may be painted upon them.

The greatest distances are chiefly made with the colour of the sky; as they grow nearer and darker, glaze and scumble the parts very thin, with such glazing shadow-colours as come nearest to the general hue of the group the objects are in. This glazing should be understood of a darkish hue; and that the first painting or dead-colour should be seen through it distinctly. On this lay, or ground, add the finishing colours.

Now, supposing this glazed ground properly adapted to the object and place, it will be easy to find the other colours, which are wanted for the lights and finishings of the same; but in laying them, you must take care not to spoil the glazing; therefore be very exact in making those colours on the pallet, and then be sure to lay them with light free touches.

Before we proceed any farther, it will be proper to say something of the most useful glazing colours.

Lake, terreverte, Prussian blue, and brown pink, are the four principal. The more you manage them like Indian ink, and the more distinctly you leave them, the better their transparent beauty will stand and appear, provided you do it with good drying oil. After these four glazing colours, burnt umber is a very good glazing warm brown, and of great use in the broken grounds and nearest parts; but the most agreeable colour for the darkest shadows, is the dark shade improved with lake. It is a fine warm shade; mixes harmoniously with all the lights, as well as the shadows; and is excellent in the trunks and bodies of trees, and in all kinds of buildings.

Make out all the ground of the objects with such glazing shadow-colours as seem nearest to the natural hue of the object in that situation; but as the principal glazing colours themselves are often too strong and glaring, they should therefore be a little changed, and softened with such colours as are of a near resemblance to themselves and the objects: thus, if it is in the distances, the terreverte and the azure, which are the principal glazing colours, may be improved and made lighter with some of the sky tints; and as the distance comes nearer with the purple. In the middle group, the terreverte and Prussian blue may be changed with some of the green tints; such as are made without white, for white is the destruction of all glazing colours. As you approach the first group, there is less occasion for changing them; but the fore-ground and its objects require all the strength and force of glazing, which the colours are capable of producing.

After this glazing ground, follow with strengthening the same in the shadows, and darkest places, in such manner as will seem easy to finish; which is the first lay of the second painting.

The colours that come next for finishing, are in the degree of middle tints: these should be carefully laid over the greatest breadth of lights, in such manner as not to spoil and cover too much of the glazing. Do it with a good body of colour, as stiff as the pencil can agreeably manage. Remember, the colours of the middle tint should be of a clean beautiful hue. According to these methods, it will be easy to finish all the second painting down from the sky, through the middle group. As you come to the first group, where all the objects should be perfectly finished, finish their under or most distant parts, before you paint any of the other, which appear nearer. Observe this method down to the last and nearest objects of the picture: and where it so happens that painting one tree over another does not please, forbear the second until the first is dry. Thin near trees of different colours will do better, if you let the under parts dry before you add the finishing colours.

Third and last painting.

If oiling is necessary, lay the least quantity that can be; which should be done with a stump tool or pencil, proportioned to the place that is to be oiled, so as to oil no more than is wanted: then wipe the whole place that is oiled, with a piece of silk handkerchief.

When going to finish any objects, remember to use a great variety of tints, very nearly of the same colour, but most of all when finishing trees. This gives a richness to the colouring, and produces harmony. The greens will fade, and grow darker; therefore it is highly necessary to improve and force them, by exaggerating the lights, and making an allowance in using them so much the lighter. For the same reason, take great care not to overcharge and spoil the beauty of the glazing; for if you do, it will be dull and heavy, and will consequently grow darker.

The method of painting near trees is, to make the first lay very near to nature, though not quite so dark, but more in the degree of a middle tint, and follow it with strengthening the shadows; then the middle tints; and last of all lay the high lights and finishing colours. All this cannot be done as it should be, at one painting; therefore the best way is, to do no more than the first lay with the faint shadows, and leave it to dry.

Then begin with improving the middle tints and shadows, and let them dry.

The third and last work is, adding all the lights and finishing colours in the best manner you are able. This method of leaving the first and second parts to dry separately, not only makes the whole much easier, and more agreeable, but leaves the colours in the greatest perfection; because most of the work may be done with scumbling and glazing, and some parts without oiling. The lights also may be laid with a better body of colour, which will not be mixed and spoiled with the wet ground.

The figures in the landscape are the last work of the picture; those in the fore-ground should be done first, and those in the distances should be done next; for after the figures in the first and farthest group are painted, it will be much easier to find the proportions of those in the middle parts of the picture. And observe, that the shadows of the figures should be of the same hue, or colour, with those of the group or place they are in.

Miniature.

The art of painting in miniature is of very antient date. It is practised either on vellum or ivory.

The best method, in painting on vellum, is to glue the edge of the vellum to a copper-plate or board, over which it is strained, in this manner: Let your vellum be every way a finger's breadth larger than what you strain it on. Moisten the fair side of the vellum with a piece of fine wet linen, and put a piece of white paper to the other side. Then apply it to the plate or board, stretching it equally in all directions, lap the edges nicely round and glue them, taking care to let no glue pass under the part of the vellum on which you mean to paint. When the glue dries, and the edges of your vellum are thus fastened, you may proceed with your work; or you may (agreeably to the practice of some painters) previously give the vellum a light wash of white lead well purified, to serve as a ground.

But ivory being the material most frequently used at present for painting in miniature, we shall here give the most approved rules for painting on ivory.

It is scarcely necessary to remark, that the first essential point towards excellence in this, as in all other branches of painting, is a thorough and well-grounded knowledge in drawing, both from plaister, and from the life; without correctness of drawing the greatest brilliancy of tints will at last be unsatisfactory. We should therefore recommend to the student in miniature, to continue, at his leisure hours, to copy from large drawings or busts, in chalks or water-colours, as correctly as possible, which is the best means of giving facility to the hand in the drawing of smaller figures.

Painting in miniature is of all others the most delicate and tedious in its process, being performed wholly with the point of the pencil. It is only fitted for works of a small size, and must be viewed near.

Colours used in miniature painting.

In painting the face, the yellows that are used are five, viz. gall-stone, terra sienna, Nottingham ochre, Roman ochre, and Naples yellow; the latter three of which are opaque colours, the other transparent. The greens are confined to one, which is sap-green. The blues are verditer, Prussian, indigo, smalt, ultramarine, and Antwerp. The reds are, carmine, drop lake, Chinese vermilion, and Indian red. Under the class of reds, may also be put burnt terra Sienna, its colour inclining much that way, though more to the orange. The only browns, if any are used in the face, are burnt umber and terra de Cassel, and they are only to be used in the mixture of dark shades.

For painting draperies, we shall only add to the above colours, lamp-black, king's yellow, and flake white.

Qualities of the above colours when used in miniature.

Yellows. Gall-stone is one of the finest and brightest colours, and a lasting one; but it should be sparingly used in the flesh tints, its brilliancy being apt to overpower all the other colours.

Terra di Sienna unburnt, is of a greasy nature, but is used as a warm yellow: burned, it is more beautiful, partaking of three tints, yellow, red, and brown.

Nottingham ochre works well; but on account of its heavy qualities must be used with caution.

Roman ochre is used with success in miniature painting, as it works, when properly portioned with gum-water, extremely sharp and neat; and being in itself a warm colour, communicates that quality to the tints it is worked in.

Naples yellow, although adopted by some artists, is of a sickly hue, and has this very bad quality, that it absorbs all colours that are either worked on it, or mixed with it.

Blues. Ultramarine excels all others in permanency.

Prussian blue has no substitute, on account of its strength of effect and transparency.

Smalt is so hard that nothing but an agate flag and muller will pulverize it sufficiently. It is not to be depended on for permanency.

Indigo is a useful blue, though it must be sparingly used, on account of its extreme depth of colour, nearly approaching to black; the best is called the rock indigo. The way to judge of its qualities is to break it, and, if good, it will have a copperish hue; but if bad, it will be of a dead blackish cast.

Verditer is a fine blue, and much used by miniature painters, not only in their sky-grounds, but likewise in the delicate parts of the face. It requires to be very finely ground on a hard flag. As to durability, it changes in time to a dirty greenish colour; on account of its being made from copper, care should be taken not to put the pencil it is used with much in the mouth, as its qualities are pernicious.

Antwerp blue, is one of the greatest deceptions in the world, being, when dry, a most beautiful bright blue; but when wet and prepared, a very dingy colour, and totally unfit for the face of a miniature. It may be used in blue draperies or back-grounds, but in nothing else.

Sap-green is a highly useful colour, when judiciously mixed with other colours; producing warm fleshy tints, which cannot be produced without it. Its extreme transparency and its permanency, are strong recommendations in its favour.

Reds. Carmine, is a fine bright crimson, inclining to the scarlet, and is rather an opaque colour: from it a variety of fine tints may be made. There are various kinds of it prepared by chemists, but the deep kind is the best, the lighter sort being frequently made so by adulteration.

Drop-lake, made from the shearings of scarlet cloth, is a pleasing crimson colour: its inclining to the purple makes it peculiarly useful for the carnation tints in painting delicate subjects.

Chinese vermilion, when good, is a bright red, and useful in miniature pictures, though not to be freely used, its opacity rendering it dangerous to mix much with other colours; but by itself, in touching the parts that require extreme brightness, it is of wonderful service. It is very difficult to find the real kind, the common vermilion, mixed with lake or carmine, being a general substitute; but the spurious and the genuine kind very materially differ in working, the former being thick and heavy, the other the contrary.

The native or mineral cinnabar, or vermilion, is likewise very fine in Spain; and the French have mines of it in Normandy. There is a method of preparing factitious cinnabar, viz. Take six ounces of sulphur, and eight of quicksilver, mix them well; then set them on the fire, till part of the sulphur is consumed, and the powder remains black; after this, it is sublimed twice in open pots, at the bottom of which the cinnabar remains very heavy, and streaked with the lines or needles, some red, and others brilliant like silver: then take it and purify it in the following manner: grind it well in fair water, on a marble, put it into a glass or earthen vessel to dry, then put urine to it, and mix it so that it be thoroughly wet and swim; then let it settle, and the cinnabar being precipitated or fallen, pour off the urine by inclination, and put fresh in the room of it, leaving it so all night, and repeating the same charge four or five days, till the cinnabar is thoroughly purified. Continue the process with beating up the white of an egg, which mixing with fair water, pour it upon the cinnabar, and stir the whole about with a walnut-tree stick; change this liquor two or three times as above, and keep the vessel close covered from dust; when used for water-colours, temper it with gum-water, and a small quantity of saffron dissolved will add to its brilliancy.

Indian red is an excellent colour, not only for touching the deep red parts, but likewise in strong flesh tints, in bright back-grounds, and draperies.

Browns. Umber is very greasy, and mixes unkindly; but, when burnt, is very useful in many parts of miniature.

Terra de Cassel, or Vandyck brown, so called from the very great estimation the inimitable painter of that name held it in, is the finest rich brown in the world; in itself producing a more beautiful colour than can be formed by the junction of any colours whatever. It is, in its natural state, rather coarse and sandy; but when prepared, it amply repays the labour.

Lamp-black is useful for mixing in hair colour and in painting draperies. The smoke of a candle received on a plate, is found the best, being blacker than the common lamp-black.

King's yellow is a bright opaque colour, admirably calculated for painting lace, gilt buttons, &c. &c. but is a rank poison, therefore should be cautiously used.

Flake white, or refined white lead, is not to be used by itself as a white, for to a certainty it will turn black, which circumstances should be nicely attended to by all artists. If used in miniature painting, for linen, &c. it should be immediately covered with a glass, which method is the only one which stands a chance of preserving its purity. For a farther account of the qualities of these colours, see Colour.

Among the above necessary colours, there are three which require to be burnt; viz. terra di Sienna, umber, and lamp-black. For this purpose, the two former are to be put in a crucible, which is to be covered and placed on a hot fire: and when you think that the lump of colour is hot through, take the crucible from the fire, and let the colour cool.

The lamp-black is to be prepared thus: Take some of the common kind; put it on a clean fire-shovel or plate of iron, over the fire; immediately on receiving the heat, it will begin to smoke, on the ceasing of which you will find your lamp-black freed from the oily substance it originally contained, and fit for immediate use.

Gum water. Choose the large white pieces of gum arabic, which are brittle and clear. Put them into a clean phial; and pour water on them, well-strained and divested of all sandy particles. Let the gum-water be about the thickness of water-gruel, that is, so thick that you can feel it in your fingers. The fresher made, the better.

Grinding the colours, and preparing them for the pallet.

Provide yourself, if possible, with an agate flag and muller; but if that cannot conveniently be had, glass ones may answer, though not quite so well. The glass muller and flag must be lightly roughened with fine flour emery, which will give it a surface that will continue a long time. After being particularly careful that your flag, &c. are quite clean, lay some of the colour to be ground on it, bruising it whilst dry, gently with the muller; then put a few drops of water on it, and grind it very carefully, not making it too wet, as that will prevent it from keeping sufficiently under the muller. When you think it is finely ground in the water, take your pallet-knife, or a thin-edged piece of ivory, scrape your colour together in a little heap on your flag, which let dry for a short time, then add your gum-water to it gradually, having a piece of ivory near you, on which you are frequently to lay some of the colour with a camel-hair pencil, thin; and if you perceive the colour in the smallest degree to shine, when dry, it is gummed enough; then you are to scrape it off your flag and transfer it to your pallet.

There are some colours which will not bear a sufficient quantity of gum to make them shine, without injuring their qualities, as smalt, ultramarine, and verditer blues.

Of hair pencils. Manner of choosing them, &c.

Pencils for painting in miniature are not made of camel's hair, but of the tips of squirrel's tails, and of these there are two kinds, the dark brown, and yellowish red. Pencils made of the latter kind are called sable pencils, and are of a stiffer nature than the others. They are a useful kind of pencil, as long as the fine flue at the end of the hair remains, on account of their elasticity; but the instant the flue is worn off, they, from their harshness, become useless; at all events, no pencil can be superior to one made of the common kind of hair. The error too prevalent amongst young miniature painters, is that of preferring a very small pencil for their work, vainly hoping, by the assistance of such a one, to execute their picture with more neatness and accuracy; but in this, they will, by experience, find themselves mistaken; the finest and most highly finished pictures being executed with a middle-sized pencil, the point of which being not only sufficiently neat, but from its body containing a quantity of colour in fluid, enables the artist to give that mellow firm touch which is so generally admired by connoisseurs in the art. The young artist should choose a middle-sized pencil, with a good spring and point, both of which he will know by drawing the pencil lightly through his mouth, and touching it on his thumb-nail; if he finds it, on being moderately wet, to spring again into its form, after being bent, it is a good sign; but as there are many pencils possessed of that quality, which are deficient in another material one, namely, that of a good point, that must be very cautiously looked to, by turning the pencil round on the nail, in every direction, observing the hairs at the point keep equally together of a length, and none shooting out on either side (which is often occasioned by the pencil-maker putting the hair into the quill with a twist in it). All these defects being carefully guarded against, you are sure of being in possession of a very principal material for miniature painting.

Ivory.

Method of choosing, bleaching, and preparing it.

Of ivory there are various kinds, the distinction of which in this art is of very material consequence. Ivory, newly cut, and full of sap, is not easily to be judged of; the general transparency it exhibits in that state, almost precluding the possibility of discovering whether it is coarse-grained or fine, streaky or the contrary, unless to the artist who, by a long course of experience, is familiarised to it. The best way to discover the quality of it is, by holding it grainways to the light, then holding it up and looking through it, still turning it from side to side, and very narrowly observing whether there are any streaks in it; this you will, unless the ivory is very freshly cut, easily discover; and in this you cannot be too particular. There is a species of ivory which is very bad for painting on, although it has no streaks in it, being of a horny coarse nature, which will never suffer the colours to be thrown out in the brilliant manner a fine species of ivory will; you are therefore not only to be cautious in choosing ivory free from streaks, but likewise that which has the finest grain and close. We shall now proceed to treat on the manner of preparing the ivory for painting on.

You are to heat a smoothing iron in so small a degree that you can hold your hand on the face of it, so long as you can reckon three or four in moderate time: then put your ivory between a clean piece of folded paper, on which place the hot iron, turning your ivory frequently, until it becomes a transparent white; for you are to observe that very particularly, an opaque white not answering for face-painting in miniature, as it would give a harshness and unpleasant appearance to your picture.

When you think your ivory is sufficiently white for your purpose, lay it under some flat weight until it cools, as that will prevent its warping. Then proceed to prepare it: for which purpose you must pound some pumice-stone in a mortar, as clear and fine as you can, which put into a fine linen or cambric bag, tying it about midway, tight, but leaving room for the pumice-dust to sift through the bottom. Then get a long mustard-bottle, perfectly clean and dry, in which suspend the pumice-dust, covering the top with the muzzle of the bag, so that nothing can come out; then shake the bottle smartly in your hand, when the fine particles of the pumice will sift out, and remain at the bottom of the bottle, thereby preventing any coarse grains from being amongst what you are going to use, which would very materially injure your ivory. Your pumice-dust being prepared, scrape the leaves of ivory with a sharp pen-knife, until the scratches of the cutting saw are entirely obliterated; then take either a piece of Dutch polishing rush, or a piece of middling fine patent glass paper, and carefully polish your ivory with it, not by passing your hand backwards and forwards, but in a circular manner, until you have it pretty level; then strew some of your pumice-dust on the ivory, and put a few drops of water on it: which done, with your muller work on it in a circular manner as before, until you find every part has equally received the pumice, which you will know by its exhibiting a dead grave appearance; those parts which have not received the pumice continuing to shine in spots, which you must still labour to do away with your pumice and muller. When you find it pumiced to your satisfaction, take a clean sponge and fair water, with which gently wash your ivory free from the pumice-dust; taking care not to rub it hard, for fear of giving the ivory a gloss that would prevent your colours from taking on it so pleasant as you could wish; after this lay your ivory to dry, and in a few hours it will be fit for use. Then paste it on a piece of wove paper, by touching the back of it merely at the edges; as gum-water, or any other cement, being put near the centre of your ivory, will cause a dark unpleasant spot perhaps to appear through, in the very part where your face is to be painted.

Instructions for mixing compound tints for the face.

Purple is formed of either ultramarine, Prussian blue, smalt, or indigo, mixed with either carmine or drop lake. Ultramarine, although the most beautiful and brilliant of colours by itself, yet in any mixture it loses that perfection, but still retains a sufficient seare of brightness to render it a desirable tint in the purplish grey shadows of the face. Prussian blue mixed as before-mentioned, makes a bright or dark purple, according as the quantities of either colours are portioned; but indigo makes still darker, owing to its great natural depth of colour. Smalt and carmine, or lake, form nearly the same tint as ultramarine, and may be used nearly for the same purposes.

Grey. Of grey tints there are various kinds, according to the subjects they are required for. A warm grey tint may be made by duly portioning burnt terra Sienna, Prussian blue, and drop lake: the more terra Sienna in it, the warmer the tint; the more Prussian blue and lake, the colder. Another grey tint, used with success by some eminent miniature painters, was composed of Prussian blue and Chinese vermilion, but on account of the unkind manner with which vermilion incorporates with any other colour, it required a greater proportion of gum than ordinary to make them work or keep together. A third grey tint, which is an excellent one, is formed of drop lake, sap green, and Prussian blue.

Olive tints. A very fine olive tint is formed of gall stone, Nottingham ochre, and carmine, or lake; and another of sap green and lake simply.

Of hair tints. A beautiful hair colour, either dark or light, according to the quantities of colours, is made of carmine, lamp-black, and sap green. The manner of forming it is only to be acquired by practice; but when once attained, will be found worth the time of the trial. That very difficult tint which is often to be met with in children's hair, by the proper junction of these colours will be produced to perfection. Other hair tints may be made of terra de Cassel simply, or by the addition of lamp-black. Some excellent painters make all their hair tints of burnt terra Sienna, lamp-black, and Nottingham ochre, the latter being added only when there is light hair wanting to be represented. Burnt umber has been substituted for terra Sienna, along with the lamp-black, and forms a good tint; but care must be taken to avoid either the greenish or reddish cast, which it is apt to produce.

Tints for fine linen, gauze, &c. Of all tints in transparent painting, such as are the miniature works of the present day, there are none more difficult to ascertain; for the delicacy not only of mixture, but the delicacy of touch, conveys the idea of beauty in the thinness and folding of fine linen or gauze, the true painting of which throws a veil over the defects in other parts of the picture. We shall therefore only observe, that any of the tints, under the head of grey, will, properly managed, answer the purpose. Having now pointed out the manner of preparing the delicate transparent tints for miniature painting, we proceed to treat of the grosser ones, namely, those for draperies.

Of colours proper for men's draperies.

We shall, under this head, make some general observations; the first of which is, that in all cloth draperies for men's portraits, it is necessary to add some flake white; as it not only gives the colour the dead appearance which cloth exhibits, but likewise its being incorporated with the flake white, gives it a body which makes the flesh tints appear to more advantage. The next observation is, that in grinding up your draperies, you are to make them appear several degrees lighter in colour than you want them to be when dry, for this reason; the flake white is a colour so very heavy, that, after you float in your coat, it will sink to the bottom, and leave your colours several degrees darker than when it was wet; and finally you are not to be too heavy or thick in floating in your draperies, but merely to see that your colour is evenly spread over the part.

There are four modes of working in miniature painting; namely, floating, washing in, handling, and marking. The first process, which is floating, and is chiefly used for draperies, is thus performed: Having marked with your pencil where your drapery is to be, grind up your colour on your flag (not putting a quantity of gum water, that would make it shine, as it would frustrate your purpose); then take a large soft hair pencil, and, having previously laid your ivory on a very level table, fill your pencil plentifully with the colour, and lay it quick all over the parts of the ivory you want covered, seeing that it runs on every part equally, which, if kept in a proper fluid state, it will readily do; then lay it in some place to dry, where it is not likely to receive dust, when you will have a fine level surface ready to work the shadows of your drapery on in a couple of hours. Washing in is performed when your picture is on your desk, by filling your pencil moderately with colour, and giving a very broad stroke rather faintly, as the contrary would not answer; this manner is chiefly used in beginning the hair, back grounds, and likewise in laying on the general flesh tint of the face. It is also used in the first touches of the dark shadows, which ought to be begun faint and broad. Handling is the manner in which all the fleshy parts of the miniature must be worked, after the first washing in; and lastly, marking consists in the sharp-spirited touches given to the different features, in order to give that animated appearance so necessary to constitute a fine picture.

Black drapery is formed of lamp-black burnt, and flake white; and must be laid in with a good deal of the latter, as otherwise it would be very difficult to manage the shadows so as to produce a pleasing effect.

Blue drapery may be made of either Prussian blue, or Antwerp blue, mixed with white; indigo being too much inclined to a blackish cast.

Green drapery is well made of king's yellow, and Prussian and Antwerp blue. The more blue, the darker the green; and the more yellow, the contrary.

Yellow drapery cannot be so well represented by any colour as king's yellow, laid thin, with a moderate quantity of gum in it.

Drab-colour is well represented by a judicious mixture of umber, in its raw state, and flake white.

A queen's brown, as it is called, is made of burnt Roman ochre, a little lamp-black and lake, with flake white amongst it.

Claret colour may be well represented by a mixture of terra de Cassel, a little lamp-black, and lake. The more black and lake, the deeper the colour.

Dark brown can be formed by a junction of Nottingham ochre, lake and lamp-black.

Lilac is made of carmine, Prussian blue and flake white.

Grey can be formed only of lamp-black, flake-white, and the smallest quantity of lake laid in very thin.

Reddish brown is best made of Indian red, very little lamp-black, and flake white.

Scarlet is a colour very difficult to lay down rules for making, as in some pictures it is dangerous to make it too bright, for fear of hurting the effect of the face, by its brilliancy catching the eye too readily; consequently, if the subject you are painting from life is very pale, you run a very great risk by annexing a very bright scarlet to his picture. We shall therefore only mention that a very bright scarlet is made of Chinese vermilion and carmine, ground together (without any flake and white); and if you want it still rendered brighter, when it is dry, fill your pencil with plain carmine, mixed with thin gum-water, and glaze over it nicely; but if, on the contrary, you wish to sadden, or take away a share of its brilliancy, add a little flake white to it, and that will have the desired effect.

Of painting the face in miniature.

You are first to provide yourself with a mahogany desk for painting on, which is a box about fourteen inches high, and a foot broad on the top; there is to be a lid covered with green cloth, which is to have a pair of small hinges at the front, and to lift occasionally with a supporting rail at the back, and notches, so as readily to adjust it to any height. About the middle of the green cloth there is to be a slip of very thin mahogany, glued at each end, but the centre of it left free, to fasten your ivory by, slipping it between the mahogany and green cloth.

The next thing you are to observe is the choice of your light, which in this kind of painting cannot be too particularly attended to; it not being like oil-painting, where the rays of the sun may be kept out by blinds, &c. without causing any material inconvenience. A north light, or as nearly as possible to it, must be attained. If there are more than one window in the room, the second must be closed, so as to admit no light; and the one you sit at is to have a green baize curtain against the lower part of it, to reach about a foot higher than your head, as you sit at your painting desk, with your left hand towards the light.

Having placed your sitter at the distance of about a yard and a half from you, begin drawing the outlines of the face; and in this be very particular, as much depends on it. When you have them drawn correctly, begin to lay in the colour, faintly, of the iris of the eye, the shadows under the eye brows in a grey tint, and under the nose rather a warm purple, in broad faint washes: ever keeping this in your mind; that you must, in the process of painting the face of a miniature picture, go on faintly at the beginning, and not hurry in your colours, as such conduct will, to a certainty, make your tints look dirty, and your picture harsh and disagreeable. Having, as before observed, laid in your grey tints where your shadows are to fall, go on heightening them by degrees, working in hatches with a middling full pencil, not too washy, nor too dry; as the former would be the means of muddying your colours, and the latter would make them raw. When you think you have pretty strongly marked out, and worked up the shadows, mix a wash of either gall stone, or Nottingham ochre, and drop lake, with which faintly go over the fleshy pasts of the face, where the shadows do not come; and then proceed to heighten the carnations on the cheeks, the colour of the beard, if any such appears, still working in the handling manner already mentioned, in various directions; so that, after some time working, the intersections appear like so many nice points or dots. Observe, as a general rule, that it is much easier to warm the tints of your face, than to cool them, by working proper colours over it. It is therefore best to begin with cool greys and purples, and towards the finishing of the picture, to add warmth, if necessary, by gradually working such colours as gall-stone, terra Sienna, or the like, over, in addition to the carmine or lake that may be necessary to produce the tint of nature.

General Observations.

From the variety of style adopted by different miniature painters, it is very difficult for a young beginner to ascertain which is best to be followed; and as there is a certain degree of mechanical attention to be paid to the management of the water-colours, to preserve them clear and free from muddiness, which is difficult to attain, we recommend to the young artist to procure a good miniature, if possible, and keep it by him, observing the style of penciling and management of the colour, at the same letting nature be his guide in the marking of his features and colouring of his picture.

In the management of back-grounds, the young painter is to observe their twofold purpose: that of giving the lights their proper value; and on the other hand, of harmonizing the colours of the face, by artfully engaging the eye with somewhat of similitude in the back-ground to a tint in the face, which otherwise, in course of working to express a particular part, might appear too prevalent.

In painting a head, on an oval piece of ivory, such as the present form of a miniature picture, draw the chin as nearly as possible in the centre of the ivory, unless the person is very tall, in which case it must be higher up; and if very short, the contrary.

Mosaic painting. This wonderful branch of art, improperly called painting, almost defying the hand of time, has been practised in many countries; but the finest works of their kind, and those by which the moderns have retrieved the art, which was in a manner lost, are those in the church of St. Agnes, formerly the temple of Bacchus, at Rome, at Pisa, Florence, and other cities of Italy.

The most esteemed among the works of the moderns are those in the church of St. Peter, at Rome. There are also very good ones at Venice.

Mosaic work is composed of small pieces of glass, marble, precious stones, &c. of various colours, cemented on a ground of stucco or mortar, in imitation of painting. It is generally employed in copying original pictures of the highest value in the art.

In performing this work, it is requisite to provide little pieces of glass of as many different colours as can possibly be got.

For this purpose a glass-maker's furnace being prepared, and the pots and crucibles full of the matter of which glass is made, put into each crucible what colour or dye you think fit, always beginning with the weakest, and augmenting the strength of the colour from crucible to crucible till you come to the deepest tincture.

When the glass has been thoroughly concocted, and the colours are in their perfection, take out the glass, hot as it is, and pour it on a smooth marble, flatting it down with another similar marble, and then cut it into slices of equal bigness, and about the thickness of an inch and a half.

Then with an instrument, which the Italians call bocca di cane, you must make some pieces square, and others of different forms and sizes, as occasion requires. These pieces are to be orderly disposed in cases, as in painting in fresco. It is usual to range all the different tints in shells, and according to their colour.

If it is desired to have gold, either in the ground of the painting, or in the ornaments or draperies, take some of the pieces of glass, formed and cut in the manner before mentioned; moisten these on one side with gum-water, and afterwards lay them over with leaf gold; then put this piece, or several pieces at a time, on a fire-shovel, and place it in the mouth of the furnace, after you have first covered them with another hollow piece of glass. Let these stand till they are just red-hot, then draw the shovel out all at once, and the gold will become so firmly attached to the glass, that it will never afterwards come off.

Now in order to apply these several pieces, and, out of them, to form a picture, in the first place provide a cartoon or design, as this is to be transferred to the ground or plaister by calking, as in painting in fresco. See Fresco.

As the plaister is to be laid thick on the wall, and therefore will continue fresh and soft for a considerable time, there may be enough prepared at once to serve for as much work as will take up three or four days.

This plaister is composed of lime made of hard stone, with brickdust very fine, gum tragacanth, and whites of eggs; and having been thus prepared and laid on the wall, and the design of what is to be represented transferred to it, take out the little pieces of glass with a pair of plyers, and range them one after another, still keeping strictly to the light, shadow, different tints and colours which are to be represented; pressing or flatting them down with a ruler, which serves both to sink them within the ground, and to render the surface even.

A long time and tedious labour are requisite to finish the work, which will be more beautiful as the pieces of glass are more uniform and ranged at an even height.

Pieces of mosaic work performed with exactness appear as smooth as a table of marble, and as finished and masterly as a painting in fresco, with this advantage, that they have a fine lustre and will last for ages.

Mosaic work of marble, and precious stones.

These two kinds of mosaic bear so near a resemblance to each other, as to the manner of working, that, to avoid repetition, we shall give them both under one, taking notice as we proceed, wherein the one differs from the other, either in the sawing or the ranging of the stones.

Mosaic work of marble is used in large works, as in pavements of churches and palaces, and in the incrustation and veneering of the walls of edifices of the same kind.

Mosaic of precious stones is only used in small works, as ornaments for altar-pieces, tables for cabinets, &c. on account of the exceeding price of the materials.

Process of mosaic painting.

The ground of mosaic works wholly marble, is usually a massive marble, either white or black.

On this ground the design is cut with a chisel, after it has been first calked.

After it has been cut of a considerable depth, i. e. an inch or more, the cavities are filled up with marble of a proper colour, (first selected according to the colours of the design, or original picture to be copied,) and reduced to the thickness of the indentures with various instruments.

To make the pieces thus inserted into the indentures cleave fast, (whose several colours are to imitate the tints of the original design,) a stucco is composed of lime and marble-dust, or a kind of mastic, which is prepared by each workman after a different manner peculiar to himself.

The figures being marked out, the painter or sculptor himself draws with a pencil the colours of the figures not determined by the ground, and in the same manner makes strokes or hatchings in the place where shadows are to be; and after he has engraven with the chisel all the strokes thus drawn, he fills them up with a black mastic, composed partly of Burgundy pitch poured on hot, taking off afterwards what is superfluous with a piece of soft stone or brick, which, together with water and beaten cement, takes away the mastic, polishes the marble, and renders the whole so even that one would imagine it only consisted of one piece.

This is the kind of mosaic work that is seen in the church of the Invalids in Paris, and the chapel at Versailles, and with which some entire apartments of that palace are incrustated.

As for mosaic work of precious stones, other and finer instruments are required than those used in marble, as drills, wheels, &c. used by lapidaries, and engravers on stone.

As none but the richest marbles and stones are used in this work, to make them go the further they are sawn into the thinnest slices or coats imaginable, scarce exceeding half a line in thickness: the block to be sawn is fastened firmly with cords on the bench, and only raised a little on a piece of wood one or two inches high.

Two iron pins, which are on one side o the block, and which serve to fasten it, are put into a vice contrived for the purpose; and with a kind of saw or bow, made of fine brass wire bent on a piece of spungy wood, together with emery steeped in water, the slice is gradually fashioned by following the stroke of the design made on paper and glued on the piece.

When there are pieces enough fastened to form any one entire part of the design, they are applied to the ground.

The ground which supports this mosaic work is usually of free-stone.

The matter with which the stones are joined together is a mastic, or a kind of stucco, laid very thin on the slices of marble, &c. as they are fashioned; this being done, the slices are applied with plyers; and if in any part they are not either squared or rounded sufficiently, so as to fit the place exactly into which they are to be inserted, they are brought down, when too large, with a brass file or rasp; and when too little, a drill, and other instruments, used by lapidaries, are used to supply the deficient part.

Manner of performing mosaic work of gypsum.

Gypsum is a kind of coarse talc, or a shining transparent stone, found in the quarries of Mont-Martre, near Paris. It is different from the plaister of Paris, but retains the name which the Romans gave to the plaister, viz. gypsum.

Of this gypsum, or stone calcined in a kiln, and beaten in a mortar, and sifted, the French have made a sort of artificial marbles, imitating precious stones, and of these they compose a kind of mosaic work, which does not come far short either of the durableness or the vivacity of the natural stones; and which, besides, has this advantage, that it admits of continued pieces or paintings of entire compartments without any visible joining.

Some make the ground of plaister of Paris, others of free-stone. If it is of plaister of Paris, they spread it in a wooden frame, of the length and breadth of the work intended, and in thickness about an inch and a half.

This frame is so contrived that the tenons being only joined to the mortises by single pins, they may be taken asunder, and the frame be dismounted, when the plaister is dry.

The frame is covered on one side with a strong linen cloth, nailed all round, which being placed horizontally with the linen at the bottom, is filled with plaister passed through a wide sieve.

When the plaister is half-dry, the frame is set up perpendicularly, and left till it is quite dry, then it is taken out by taking the frame to pieces.

In this kind of mosaic the ground is the most important part.

Now, in order to the preparation of this sifted gypsum, which is to be applied on this ground, it should be dissolved and boiled in the best English glue, and mixed with the colour that it is to be of; then the whole is to be worked up together in the usual consistence of plaister, and then taken and spread on the ground five or six inches thick.

Observe, that if the work is such that mouldings are required, they are to be formed with gouges and other proper instruments.

It is on this plaister, thus coloured like marble or precious stone, and which is to serve as a ground to a work, either of lapis, agate, alabaster, or the like, that the design to be represented is drawn, having first been pounced or calked.

To hollow or impress the design, you must use the same instruments that sculptors do, the ground whereon you are to work not being much less hard than marble itself.

The cavities being thus made in the ground, are to be filled up with the same gypsum boiled in glue, only differently coloured, and thus are the different colours of the original represented.

In order that the necessary colours and tints may be ready at hand, quantities of the gypsum must be tempered with the several colours in pots.

After the design has been thus filled and rendered visible, by half-polishing it with brick and soft stone, it is to be gone over again, cutting such plates as are either to be weaker or more shadowed, and filling them with gypsum; which work is repeated till all the colours being added one after the other, represent the original perfectly.

When the work is finished, it is scoured with soft stone, sand, and water; after that, with a pumice-stone; and, in the last place, polished with a wooden mullet and emery.

Then, lastly, it is smeared over with oil, and rubbed a long time with the palm of the hand, which gives it a lustre no ways inferior to that of natural marble.

If you would only make a variegated table, or other work, of several colours, without mosaic figures, the process is somewhat different.

Then you are to prepare separately, in bowls, as many colours as nature shews in the marble which you would imitate; and after you have incorporated these with gypsum and glue-water, take a trowelful of each and dispose them in a trough without any order; then, without mingling them, and only by cutting or crossing the gypsum of each trowel once with each of the rest, you will give them the appearance of beautiful natural marble. Of these you may make tables, or lay them in a mould, according to the nature of the work.

Elydoric painting.

This new method of painting was invented by M. Vincent, of Montpetit. It is little known. It takes its name from two Greek words, expressing oil and water, both these liquids being employed in its execution.

Its principal advantages are, that the artist is able to add to the mellowness of oil-painting, the freshness of water-colours, and the high finishing of miniature, in such a manner that the work appears like a large picture seen through a diminishing glass.

The following is the manner of proceeding: A piece of very fine linen or white taffety is sized with starch in the most equal manner possible; or pieces of glass about two inches square, the angles of which are blunted in order that the cloth may be without wrinkles.

When these pieces of cloth are sufficiently dry, a layer of white lead finely ground in oil of pinks or poppies (the whitest that can be procured) is applied on them with a knife. To this layer, when dry enough to admit of scraping, more may be added if necessary.

As it is of the greatest importance for the preservation of this kind of painting, that the layers are purged of oil, in order that they may imbibe the colours laid on them, it is necessary that their surface is made very smooth, and is very dry and hard.

The artist is next provided with a circle of copper, nearly two inches in diameter, and one-fourth of an inch in height, extremely thin, and painted on the inside with black. This circle is employed to contain the water on the surface of the picture.

Water distilled from rain or snow is preferable to any other; ordinary water, on account of the salts which it contains, being pernicious to this mode of painting.

The colours, also, must be ground between two Oriental agates, most carefully preserved from dust; and mixed with oil of poppies, or any other siccative oil, which has been extracted without fire, and limpid as water.

All the colours being ground, are placed in a small heap, on a piece of glass covered with distilled water, in a tin box.

The materials being thus prepared, the subject to be painted is faintly traced with a black-lead pencil on one of the pieces of cloth above-mentioned.

The tints are formed on the pallet from the little heaps under the water, and the pallet placed as usual in the left hand.

The picture is held between the thumb and fore finger, supported by the middle, and the necessary pencils between the third and little fingers. The hand rests on the back of a chair, to give a full liberty of bringing the work near, or removing it from, the eye.

The pencils are cleaned with essence of rectified turpentine.

After having made the rough draught with the colours still fresh, the circle of copper which ought to surround the picture is fitted exactly to the surface.

The distilled water is poured within this circle till it rises to the height of one-eighth of an inch, and the eye is held perpendicular over the object. The third finger of the right hand must rest on the internal right angle of the picture.

The artist retouches his work, adding colour and softening as he finds requisite.

As soon as the oil swims on the top, the water is poured off, and the picture carefully covered with a watch-glass, and dried in a box by a gentle heat.

When it is dry enough to be scraped nearly smooth with a knife, the artist repeats the same method till he is satisfied with his work.

It is at this period that the advantage of this new method particularly shews itself for the purpose of finishing; as the water poured on the picture discovers every fault of the pencil, and gives the power of correcting and perfecting with certainty.

When the work is finished, it is put under a crystal, from which the external air is excluded, and it is then dried by means of a gentle heat.

HISTORY OF PAINTING.

Rise, progress, and decline of the art among the antients.

As far as history reaches back into past ages, it presents us with manifest proofs of the antiquity of painting and the other arts of design. The first writers of history were in no little degree indebted to those arts for their best materials and surest vouchers in compiling their records: painting, sculpture, and other monuments, having been employed in the most antient times to preserve the memory of facts, and likewise to represent religious and philosophical opinions.

It is natural to imagine that a certain rude way of delineating objects has in all countries preceded the more artificial communication of the thoughts by letters, and hence we hear of the picture-writing of the Mexicans, and the hieroglyphic symbols of Egypt.

Pliny expressly says that the art of painting was unknown in the times described by Homer, the most antient of authors, in the Iliad; but he acknowledges that sculpture was in use at the siege of Troy, from whence it is evident that design, which is the basis and essential part of painting, was even then well understood. Although the name of the art is not to be found in the writings of Homer, yet the art itself is there plainly described, as it consists in design and colouring. We can, therefore, hardly doubt that painting was practised even at that early period; at least, Homer himself must be allowed by every one who reads his lively descriptions of carvings, statues, sculptures, tapestries, and picturesque ornaments of all kinds, to have had very perfect ideas of all the arts of design, not only of statuary and sculpture, but of painting.

But the earliest date of painting appears to have been in Persia, India, and China, if we give credit to the writers of those countries. Neither the Persians, however, nor the Chinese, appear to have at any time attained to excellence in painting. The former, as well as the Arabians, had, at one period, some knowledge of mosaic, and their carpets, worked with various figures, were in high estimation in the time of Alexander the Great; but all such productions are of an inferior class, as they must necessarily be copied from other works. Painting, among the modern Persians, is still in the same low degree.

The Chinese paintings have little other merit than the brightness of their colours. The pictures of the Chinese artists are totally deficient in drawing and perspective.

In India, painting appears to have been confined in the earliest times to the representation of monstrous forms, connected with the superstition of the country. The paintings of Thibet are said to be remarkable for the fineness of the penciling, but to have no other merit. Some of the idols are painted in imitation of relievo, but are wholly destitute of beauty.

In Egypt, according to the accounts given by Plato, painting had been practised for several thousand years before his time, but we do not know with what degree of progress. The monuments of Egyptian painting, says Winckelman, with which we are best acquainted, are the chests of their mummies, which have endured so long that they appear to be secure from the injuries of time. That learned antiquarian gives the following account of the method of painting used on these chests:

"White, made of white lead, is first laid on as a ground, and the outlines of the figure are traced on this ground with black. The colours afterwards used are four in number, namely, blue, red, yellow, and green, and these are laid on without any mixture or shading. The red and blue prevail most, and seem to have been prepared in the coarsest manner. The light is formed by leaving the white-lead ground, where it is necessary, in the same manner as white paper is treated in drawings."

In the travels of Norden in Upper Egypt, there is a description of some colossal figures, coloured in the same manner as the mummies. The colours are laid on a ground prepared in the manner of fresco, and they are said to have retained their freshness for many thousand years.

The painting of the chests of mummies, of earthen-ware, and of ornaments on their barges, appears to have been the chief employment of the Egyptian artists. Pliny relates that they painted also on the precious metals, but in what manner they exercised this latter branch of art is unknown.

This style of Egyptian painting is supposed to have continued till the reign of the Ptolemies.

In antient Etruria, now called Tuscany, the arts flourished at a very early period. Pliny says that painting was carried to great perfection in Italy before the foundation of Rome; and it appears that even in his time the painters of Etruria were held in great esteem.

The only Etrurian paintings which are now remaining were found in the tomb of the Tarquins. They consist of long painted frizes, and pilasters adorned with large figures which occupied the whole space from the base to the cornice. These paintings are on a ground of thick mortar, and many of them in a high state of preservation.

Winckelman is of opinion, that in Campania also the arts had been introduced by the colonies of Greeks who settled at Naples and Nola; but considers as purely Campanian works some medals of Capua and Teanum, whither the Greeks had not reached, and praises the beauty of several. The authority, however, of these medals is questioned.

There have been discovered also, says the learned abbé, a great number of painted Campanian vases, which, for design, are worthy of a place in the works of Raffael, and give us a high idea of the perfection of antient art.

But it is in Greece that the history of painting is first deserving of particular attention. The Greeks have, with most singular diligence, preserved the names of their artists from the earliest introduction of the arts amongst them. Ardices of Corinth, and Telephanes and Crato of Sicyon, are noticed at a period when painting had advanced no farther than the mere circumscription of shadows by single lines. To this mode of design they gave the name of sciographia. Those artists taught something of the effect of light and shade, and of course gave an appearance of roundness to the object represented. This step of art was first called graphice. To these succeeded the monochromatists, a numerous list; the first of whom was Cleophantes the Corinthian, who filled up his outline with a single colour, every where of equal force, and thence gave the name of monochroms (or objects of one colour) to his paintings.

Cimon Cleonæus invented the art of varying the attitudes of his figures, distinguishing the joints and muscles, and imitating the folds of draperies. But the highest encomium given of him by Ælian, is that he somewhat improved the rude art of his time.

The antient schools were those of Sicyon, Rhodes, Corinth, and Athens. Pliny mentions that the authority of Eupompus, an artist of Sicyon, was of so great weight that, whereas before him there were only two schools, the Asiatic and the Grecian, they were from his time divided into three, the Attic, Sicyonian, and Ionic.

Aglaophon and Polygnotus of Thasos, who lived about 420 years before Christ, were the first painters of eminence. Polygnotus is said to have been the first who gave a pleasing air to the draperies and head-dresses of his female figures, and to have opened the mouth so far as to shew the beauty of the teeth. Aristotle speaks of him as excellent in expression. But the art of painting may be still considered to have been in an inferior state till the time of Timanthes, Parrhasius, and Zeuxis, who flourished about the period of the Peloponnesian war.

In the contest between the two latter of these great painters, Zeuxis declared himself to be overcome, because a cluster of grapes, painted by him, had only deceived the birds, but he was himself deceived by a curtain painted by his rival. The principal works of Zeuxis, according to Pliny, were his Penelope, in which he appeared to have expressed the manners of that princess; a Jupiter surrounded by the gods; the infant Hercules strangling the serpents in the presence of Amphitryon and Alcmene; Helen; and Marsyas bound by Apollo. Lucian also gives an account of a picture by Zeuxis, representing male and female centaurs; in describing which, after speaking of the composition itself, he proceeds to notice the execution of the work: and praises particularly the truth and delicacy of the drawing, the perfect blending of the colours, the skilful shading, and the scientific observance of proportion and harmony throughout the whole performance.

Parrhasius was esteemed superior to others in correctness of outline and softness of colouring. Timanthes is chiefly celebrated for expression, and, in particular, for his picture of the sacrifice of Iphigenia; in which he covered the face of Agamemnon with a mantle, because he thought it impossible to represent any expression adequate to the feelings of his situation.

The fame of these great artists was surpassed by the class of painters who immediately succeeded them. Protogenes, Pamphilus, Melanthius, Antiphilus, Theon, Euphranor, and, finally, Apelles, carried the art of painting to the utmost perfection which it has ever attained. These were chiefly eminent in separate provinces of art. Euphranor united a great skill in various branches, and Apelles eclipsed all other painters in his powers of giving elegance and grace to his figures.

From the time of these pre-eminent masters, painting gradually declined in Greece; and, the Romans becoming masters of the whole country, the arts sunk into insipidity and insignificance.

The undisputed and unrivalled excellence of the Greek schools appears to have consisted in drawing and expression. None of their greatest works remaining to our time, we can only take the accounts of historians respecting their powers of colouring; but it is evident that they were capable of making very nice distinctions in this branch of art, from the comparison made between two pictures of Theseus, painted by different artists, in one of which the hero was said to appear as if he had been fed on roses, and in the other on flesh.

It is still more particularly doubtful whether the antients possessed the knowledge of chiaro-scuro in so eminent a degree as it has since been shewn in the works of the Lombard and Flemish schools. The present remains of antient paintings do not certainly warrant any conclusion in their favour, although many passages in their historians tend to make us believe them skilled in this point; and, as the works that remain are undoubtedly executed by inferior artists, their authority may be thought of little weight against the general testimony on the contrary side.

The character of the antient school of art is thus given by a Greek writer:

"The paintings of the antients," says Dionysius of Halicarnassus, "were at first simple and unvaried in their colouring, but correct in their drawing, and distinguished by their elegance. Those which succeeded, less correct in their drawing, were more finished; more varied in their light and shades, trusting their effect to the multitude of their colours."

Roman art. We have already seen that before the foundation of Rome the arts were cultivated in Etruria. Pliny also mentions some paintings at Ardeæ, Lanuvium, and Cære, older than Rome, but it is uncertain by what artists these were executed. As long as the Romans employed artists of other countries, they were indifferent to the cultivation of the arts; but towards the year of Rome 450, and 303 years before Christ, one of the Fabii, a patrician family in Rome, thought it no discredit to employ himself in painting. He painted the temple of the goddess Salus, and assumed the name of Fabius Pictor, or the painter. His works remained till the temple itself was destroyed by fire in the reign of Claudius.

The example of Fabius did not excite imitation. More than a century elapsed before the tragic poet Pacuvius followed his example, and painted the temple of Hercules. Turpilius, a Roman knight, was also a painter, contemporary with Pacuvius. Painting did not come into great repute till the time of Messala, who, as well as Lucius Scipio, painted representations of his own victories. Few names of Roman painters, even in the time of Augustus, are mentioned by writers. The arts, however, flourished in high reputation under many of the emperors, particularly from the time of Nerva to Antoninus; and Nero is said to have prided himself on his skill in painting. A colossal painting of 120 feet in height was executed by his orders, and was afterwards destroyed by lightning. This was the only work which is particularly mentioned by antient authors to have been painted on cloth.

In the time of Claudius and Nero, the arts had considerably degenerated, and in the decline and fall of the Roman empire they were neglected and lost for many centuries.

The best authority to be consulted on the state of Grecian and Roman painting, is the relation of Pliny in his 35th book of natural history; where the reader will find a complete list of the Greek and Roman painters, and of their works, arranged in their due classes of merit.

Ælian, Pausanias, Quinctilian, Velleius Paterculus, and Cicero, may also be referred to for instructive accounts of various works of the Greek masters.

Of the methods of painting, and colours employed by the antients.

The paintings of the antient artists were either moveable, or on the ceilings or compartments of buildings. According to Pliny, the most eminent painters were employed on moveable pictures. The latter were either on fir-wood, larch, box-wood, or canvas, as in the instance of the colossal picture mentioned above, and sometimes on marble. When they employed wood, they laid on first a white ground. Among the antiquities of Herculaneum are four paintings on white marble.

Their immoveable paintings on walls were either in fresco, or on the dry stucco in distemper. Indeed, all the antient paintings may be reduced to, first, fresco-painting; secondly, water-colour or distemper-painting; and thirdly, encaustic painting.

The antient fresco-paintings appear to have been always on a white stucco-ground. The outlines of the antient paintings on fresco, were probably done at once, as appears from the depth of the incision, and the boldness and freedom of the design.

In general, the antients painted on a dry ground, even in their buildings, as appears from the Herculaneum antiquities, most of which are executed in this manner. At Rome and Naples, the first (deepest) coat is of true Puzzolana (of the same nature with the terras now used in mortar, required to keep out wet), about one finger thick; the next of ground marble, or alabaster, and sometimes of pure lime or stucco, in thickness about one-third of the former. Upon this they appear to have laid a coat of black, and then another of red paint; on which last the subject itself was executed. Such seems to have been their method of painting on walls; but in their moveable pictures, and in the performances of their first artists, and where effect of shade and light was necessary, they doubtless used white.

The colours employed, they seem to have mixed up with size: this appears to have made the colours so durable and adhesive, that the ancient paintings lately found, bear washing with a soft cloth and water, and sometimes even diluted aquafortis is employed to clean their paintings in fresco. Pliny says, that glue dissolved in vinegar, and then dried, is not again soluble.

What the encaustic painting of the antients was, has been much disputed. From the works of Vitruvius and Pliny, it appears evidently that it was of three kinds:

First, where a picture painted in the common way, was covered with a varnish of wax melted, diluted with a little oil, and laid on warm with a brush;

Secondly, where the colours themselves were mixed up with melted wax, and the mixture used while warm; and

Thirdly, where a painting was executed on ivory by means of the cestrum or viriculum.

Some experiments on this last method by Mr. Colebrook may be found in the Phil. Trans. vol. 51 and more particular directions in Muntz's treatise on encaustic painting. See Encaustic.

It appears from antient writings of the best authority, that in the earliest and purest times of this art, the painters used few colours, perhaps not more than four. But no certain conclusion can be drawn, that the more early among the great painters of the antients, such as Apollodorus, Zeuxis, Timanthes, &c. had no more colours than four to use, merely because they did not use them. On the contrary, it may be conjectured with some degree of probability, from their chasteness in design, and from the complaints Pliny makes of the gaudy taste of the Roman painters, that the Greeks in general were designedly chaste in their colouring, and not so merely from necessity.

Of white colouring substances, the antients had white lead variously prepared, a white from calcined egg-shells, and a preparation from cretaceous and argillaceous earths. The moderns, in addition, have magistery of bismuth, little used; and ought to have the calces of tin and zinc.

Of blacks, the antients had preparations similar to lamp, ivory, blue, and Frankfort black; also to Indian ink, and common writing ink; and they used what we do not, the precipitate of the black-dyers' vats.

The antients possessed a species of vermilion, or fine cinnabar, a coarser cinnabar, red lead; various earths burnt and unburnt, apparently similar to our red ochre; Venetian red, Indian red, Spanish brown, burnt terra di Sienna, and scarlet ochre; they had also a substance alike in colour and in name to our dragon's-blood. See Colours.

The yellow pigments of the antients were generally the same with our orpiments, king's yellow, Naples' yellow, &c. They did not possess turbeth mineral, mineral yellow, or gamboge; nor do they appear to have known of gall-stone as a pigment.

Of blue paints they had preparations from the lapis syanus, and lapis armenus. Indigo they had, and perhaps bice and smalt; for they made blue glass, but whether from some ore of cobalt or of wolfram must be uncertain; they had not Prussian blue, verditer, nor litmus, which we have. We do not use the blue precipitate of the dyers' vats, nor mountain blue, which they certainly employed.

Of green colours they had verdigris, terra vert, and malachite, or mountain green. The latter is not in use among us. Sap green, green verditer, and Scheeld's green, appear to have been known to them: like us, they procured as many tints as they pleased, from blue and yellow vegetables.

We have no original purple in use: that from gold, by means of tin, though very good when well prepared, is too dear perhaps, and unnecessary. Their purple was a tinged earth. Their orange of Sandarac, (red orpiment) we also possess. Hence there does not appear to have been any great want of pigments, or any material difference between the colours they used, and such as we generally employ. Perhaps the full effect of colouring may be obtained without the use of exceeding brilliant pigments, depending chiefly on the proportion and opposition of tints.

The antients could not know any thing about the spirit varnishes, distillation being a modern invention; but they were undoubtedly acquainted with the use of the better oil varnishes, that is, with the use and effect of resinous gums, dissolved in boiling inspissated oils.

One of the best preserved mummies in the British Museum, has an astonishing brightness of colours on the outside of the coffin. Thousands of years have not impaired them; they are as fresh as if they had been laid on yesterday.

From an accurate observation of one of those mummies belonging to the university of Cambridge, it appeared that the varnish which covered the colours could not be dissolved, nor in the least affected by common water, and that it equally resisted the dissolving powers of the strongest spirits; hence it is reasonable to conclude, that the coffins of the mummies were not covered with size, whites of eggs, simple gums, or any preparation of wax, but with a fine transparent oil-varnish. It was discovered at the same time, the colours themselves were not prepared or mixed with oil; for where the external glossy skin was damaged, broken, or rubbed off, even common water would wash the colours away, and affect the chalk ground under them.

Pliny has described the general and particular effects of the varnish of Apelles, under the name of atrament, so distinctly, that nobody can mistake the thing, or the mixture he is speaking of. He has mentioned the shining glossy skin of the varnish, which excites the brightness of the colours, and preserves them against dust; he observed, that this skin was laid on so thin, that it could not be discerned at any distance; nor was he less accurate in reporting the particular effects of that mixture which Apelles made use of; it harmonized, and lowered the tone of the brightest florid colours in an imperceptible manner, and the whole appeared as if it had been seen through isinglass. The chemists and connoisseurs are fully of opinion that no liquid substance or mixture of any kind is fit to produce these effects besides the oil-varnishes; and if there are not, Apelles and the Greeks were certainly acquainted with these varnishes: a fact, which might be strongly urged in behalf of their knowledge of colours.

The black outlines of the figures of the most ancient Greek paintings yet extant, that is, on Etruscan vases, are so sharp, so thick, and drawn in so easy and masterly a manner, that one cannot help looking upon them as having been drawn in oil-colours. Had they been in distemper or water-colours on the red clay ground on which they are applied, they would have been imbibed and soaked into it. Our china and enamel painters, prepare and apply their colours with spike or other liquid oils; and the Greek masters seem to have done the same, unless they should appear to have burnt their vases before they painted them, or to have used a mixture of dissolved wax or gum for giving a body to their colours, which might have answered the same end as oils. And this is the more probable, as there is some reason to believe, that these vases went through two different fires, that of baking them, and that of smelting or burning-in their colours.

The Greek and Roman paintings that have been preserved or discovered at Rome and Herculaneum do not countenance the supposition of oil-colours. On the other hand, Vitruvius, who has left us so many valuable notices of the antient arts, acquaints us that there was a kind of painting, which absolutely required a mixture of oil.

From these observations, the evidence which the antients have given us in behalf of themselves, and of their knowledge of oil-painting, may be summed up in few words.

Their having been acquainted with the white chalk ground which many modern masters use for oil-painting on boards, proves no more than that the antients might have done the same.

The oil-varnishes used by the Egyptians and Apelles might have brought them to the discovery of oil-painting; but as it appears both from mummies, and from the works of Pliny, that their colours were not prepared and mixed with that varnish, and as it is plain rather that this varnish was externally laid over the finished pictures, no other conclusion can be drawn, except that they were within sight of the discovery, and that it is a matter of wonder that they should not have laid hold of it.

The outlines of the old Greek or Etruscan vases are merely fallacious appearances.

The old Greek and Roman paintings on walls and stones are either painted in distemper or fresco, or they have not been sufficiently examined.

The oil used in the coarser wax and wall paintings, proves at most, that experiments had been tried with oils; but we have no direct proofs of oil-painting having been understood or used by the Egyptians, Greeks, or Romans; and however great their skill or ingenuity, they might very well have been within sight and reach of the discovery, and nevertheless have missed it.

Rise and progress of painting among the moderns.

Italy. The revival of painting in Italy was owing to Giovanni Cimabue, born at Florence in the year 1240 He acquired his first instructions from some inferior Greek painters then employed in that city, and laid the foundation of the art in his own country.

His immediate followers were Giotto and his scholars, whose manner, like that of their master, was dry and hard; but the admiration bestowed on their works excited a general emulation, and they were succeeded by Masolini and Masaccio, the latter of whom began to advance the art by giving a superior air to his figures. Ghirlandaio added a greater knowledge of distribution in the subjects of his pictures, as well as greater correctness of design.

Andrea Castagna was the first Florentine who painted in oil. But Lionarda da Vinci, and Michael Angelo Buonaroti, were the glory of the Florentine art. Lionardi, possessing a fine imagination, and full of sensibility, entered into all the details of painting, and devoted himself to the expression of the affections of the soul. If, in this sublime branch of the art, he was afterwards surpassed by Raffaele, he could at least boast not only of excelling all the painters who went before him, but of having pursued and investigated a path which none of them had attempted to enter. His design is remarkable for purity, and the most diligent exactness of forms.

Michael Angelo delighted in seeking the great and the terrible, rather than the graceful and pleasing. Being well acquainted with every part of anatomy, he knew more accurately than any other artist in what manner to express the forms and joinings of the bones, and the office of every muscle, its origin and insertion. "In his figures," says Mengs, "the articulations of the muscles are so easy and free, that they appear to be made for the attitude in which he represents them." His style possessed a degree of grandeur beyond any other painter. He did not possess, in the opinion of Reynolds, so many delightful parts of the art as Raffaele, but those which he had acquired were of a more sublime nature.

He informs us in one of his letters (continues sir Joshua), that he modelled in clay, or in wax, all the figures which he intended to paint, a method familiar to the painters of that time.

Vasari has recorded that he painted but one picture in oil, and resolved never to paint another; saying it was an employment for women and children.

Michael Angelo was born at Castel Caprese in Tuscany in 1474, and died at the age of ninety. His principal work is the capella Sistina in the Vatican, which was painted by order of pope Julius the Second. It represents, in various compartments, the origin of the human race, and its progress to society; the empire of religion; and the last judgment.

The contemporary of Lionardo da Vinci, was Pietro Perugino, the master of Raffaelle Sanzio d'Urbino.

Raffaele was born in 1483, and was at an early age the pupil of Pietro. His first manner was that of his master; but endowed with a transcendant genius, after carefully studying, and uniting in himself, all the excellences of his predecessors and contemporaries, he formed a style more perfect than that of any painter who went before, or has succeeded him. He was sent for to Rome by pope Julius the Second, who employed him to paint several apartments of the Vatican palace.

It was fortunate for Raffaele, says Mengs, that he was born in what he terms the infancy of the art, and that he formed himself by copying nature, before he had access to the works of any great master. He began by studying, with great exactness, the simple truth in his figures; and thus habituated to imitate nature with precision, it was not difficult for him to carry the same accuracy into the superior style which he adopted, first on the sight of the works of the great Florentine masters, and afterwards in imitation of the antients.

Composition and expression are the chief excellences of Raffaele. He had too high an idea of painting to consider it as a mute art: he made it speak to the heart; and this could only be done in subjects which required expression. If Raffaele did not attain an excellence equal to the Greeks, he saw, at least, and imitated, whatever was most beautiful and expressive in nature. "The Grecians sailed majestically," says Mengs, "between earth and heaven; Raffaele walked with propriety on the earth."

At *Venice*, about the same time with Lionardo da Vinci, flourished the Bellinis and Mantegna. Giovanni Bellini contributed greatly to the progress of painting. He is accounted the founder of the Venetian school, by introducing the practice of oil-painting, which he managed very skilfully, and by teaching his scholars to paint after nature. He gave a noble air to his heads, and there is somewhat of harmony in his pictures; but his greatest glory is that he was the master of Giorgione and Titiano Vecelli, who carried the Venetian colouring to perfection.

Giorgione died in his 32d year, having excited the emulation of Titian, who soon greatly surpassed him.

Titian was instructed to copy nature in the most servile manner in the school of Bellini, but after seeing the works of Giorgione, he conceived the ideal excellence of colouring. The beauties of his works are to be found in the happy disposition of colours, both proper and local, an art which he carried to the extreme of skill. The artists in the Florentine and Roman schools had painted chiefly in fresco and distemper, and finished their large works from previous sketches; but as Titian painted in oil, and finished directly from the objects in nature, this practice, joined to his natural talents, gave him extraordinary advantages, and the greatest truth to his pictures.

He is not eminent in historical pictures alone, but also in landscape. In this province his scenes are well chosen, his trees are bold and varied in their forms, and their foliage admirably executed. He generally selected for his landscapes some singular appearance of nature.

In *Lombardy*, about the same period also, Bianchi, born at Modena, instructed in painting Antonio Allegri, better known by the name of Correggio. Correggio began, like the other painters of his time, to imitate nature alone, but soon enlarged his manner, and gave ease and grandeur to his designs. He painted chiefly in oil, a kind of painting susceptible of the greatest delicacy and sweetness, and he gave a pleasing and captivating tone to his pictures. His method was to lay his colours very thick on the brightest parts of his pictures, in order to make them capable of receiving afterwards the highest degree of light. He perceived that the reflections of light correspond with the colour of the body which reflects them, and on these principles founded his system of colouring.

A delicate taste in colours, a perfect knowledge of chiaro-scuro, the art of uniting light to light and shade to shade, together with that of detaching all objects from their ground, and an inimitable harmony of design, placed Correggio in the class of the greatest masters whom Italy has known.

From these great masters descended the schools of Florence, Rome, Venice, and Lombardy, in which the most distinguished painters were Fra Bartolomeo di San Marco, Andrea del Sarto, Giulio Romano, Vasari, Polydoro, Michael Angelo da Caravaggio, Tintoretto, Paolo Veronese, the Bassans, Pordenone, Parmigiano, and lastly, the Carraccis, who combining the merits of the various schools, became themselves the head of a school called the Bolognese school, from the place of their birth.

Ludovico Carracci was the master of the other two, Annibale and Agostino. He had studied the works of Titian and Paolo Veronese at Venice, those of Andrea del Sarto at Florence, those of Correggio at Parma, and those of Giulio Romano at Mantua; but he chiefly endeavoured to imitate the manner of Correggio.

Annibale studied equally Correggio and Titian, but he is principally esteemed for his knowledge of design. Agostino possessed a mind greatly cultivated by learning, and he devoted part of his time to poetry and music. These three painters often united their skill in the performance of the same picture, and their works are often confounded together, although the style of each is strongly different from the other two. Ludovico had less fire, but more gracefulness and grandeur; Agostino's conceptions were more spirited; and Annibale is characterized by boldness, by a more profound design, and a more powerful readiness of execution. "Ludovico," says sir Joshua Reynolds, "appears, in his best works, to approach the nearest to perfection. His unaffected breadth of light and shadow, the simplicity of colouring, and the solemn effect of that twilight which is diffused over his pictures, appear to correspond with grave and dignified subjects better than the more artificial brilliancy of sunshine, which enlightens the pictures of Titian.

The Carraccis established an academy at Bologna, which their zeal for the arts induced them at first to call l'Academia deè Desiderosi, but it was soon called by the name of the founders, because none more honourable could be given to it. In the schools of this academy were taught the art of modelling, perspective, and anatomy; lessons were given on the beauty of the proportions of nature, on the best manner of applying colours, and on the principles of light and shade. They held frequent meetings, to which men of general learning were admitted; but these meetings ceased on the departure of Annibale, when he went to Rome to paint the gallery of the cardinal Farnese.

The most eminent succeeding painters of the Bolognese school, were Guido, Lanfranco, Albano, and Guercino. Guido is distinguished by the gracefulness of his style, and Guercino by boldness of colour and effect.

In the Roman school, Pietro da Cortona succeeded to those great imitators of their predecessors and nature; and finding it difficult to rival them in that kind of painting, he applied himself principally to composition, and the arrangement of numerous groups. His contemporary and rival was Andrea Sacchi, followed by Carlo Maratti, who flourished at Rome about the middle of the 17th century, and aiming at extraordinary perfection, diligently studied the works of the greatest painters, and particularly Raffaele and the school of the Carracci. He is the last eminent painter of the Roman school. His best disciple was Francesco Imperiale, after whom Pompeo Battoni is the only one with whose works we are acquainted.

At Naples, in the early part of the 17th century, Guiseppe Ribera, called Spagnoletto, painted in the style of Caravaggio, and surpassed him in invention, design, and choice of subject. Luca Giordano was his disciple, who afterwards studied under Pietro da Cortona at Rome, and returning to Naples, became the founder of the Neapolitan school. Of this school Solimeni and Sebastian Conca are the principal ornaments.

During the fourteenth and fifteenth centuries, painting began to appear anew in Germany, France, Holland, and Flanders.

Germany. The names of Albert Durer, Kranach, Holbein, and Amberger, stood high at Nuremberg, Augsburg, Basil, and Weimar, in the beginning of the 16th century, but the capital of Vienna afforded no encouragement to painting till the reign of Rodolph the Second. The succeeding monarchs, principally from Ferdinand the Third to Leopold the First, were great promoters of the arts; but the perpetual wars in which they were involved, prevented the progress of refinement; and it was not till the total repulse of the Turks from the Austrian frontiers, under the last of these princes, that painting began to flourish at Vienna. The artists of the German school are numerous, but few of them have risen to eminence. Of those few, Albert Durer is the first in the order of time, and Mengs the latest.

Albert was born in 1471, and excelled in painting and engraving. His pictures were finished with great exactness, but his manner was dry and hard. His principal works were painted at Prague in the palace of the emperor Maximilian, by whom, as well as by Charles the Fifth, he was held in great esteem. Raffaele is said to have hung the prints of Albert Durer in his own apartment.

Holbein was nearly contemporary with Durer. He is known by a multitude of accurate portraits, and was likewise eminent for richness of invention, which he displayed in numerous designs for gravers, sculptors, and jewellers. His Dance of Death, painted in the town-hall of Basle, is universally celebrated. He is remarkable for having, like Turpilius, the Roman, performed all his works with his left hand.

Kneller, born at Lubeck, in the duchy of Holstein, received his first instructions from Rembrandt. He painted chiefly portraits, which were highly celebrated in England during the reigns of Charles the Second, James the Second, William the Third, Anne, and George the First.

Antonio Raffäel Mengs, one of the most scientific painters of any country, was educated in Germany; but painted chiefly at Rome, and at Madrid; to which latter capital he was invited by Charles the Third. He practised his art with an extreme diligence, which has deservedly rendered him eminent. His works possess many beauties of composition, and mechanical execution. His writings are too frequently metaphysical, but contain many excellent disquisitions on painting, calculated to inspire the artist with exalted ideas of his profession.

Holland and Flanders. The Dutch and Flemish schools are nearly as much distinguished by the number, as by the excellence of their artists.

In the former school, the precedence of fame in point of date, is given to Lucas van Leyden, born in 1494. He was a laborious competitor of Albert Durer, and resembles him in manner and style.

Polemberg, Ostade, Gerard Dow, Mieris, Wouvermans, Cuyp, Berghem, Vanderwerf, Van Huysum, Schalchen, Brower, Hemskirk, are amongst the eminent painters of the Dutch school; but they are all greatly surpassed by the truly astonishing genius of Rembrandt, many of whose works seem even to surpass nature in force and effect. His etchings also are highly and deservedly valued. It is not, however, to be omitted, that the singular merit of his original conceptions and compositions is counterbalanced by the grossness of his forms.

The honour of founding the Flemish school is attributed to John of Bruges; and the names of his successors are too many to admit of detail. Their works are to be found in every cabinet. The most illustrious masters of this school are Rubens and Vandyck.

To John of Bruges, better known by the name of John van Eyk, was for a long time attributed the invention of oil-painting; but he had only the honou of transmitting that method to Italy, where a picture painted by him, and sent to Alphonso, king of Naples, first divulged the discovery. Frans Floris is celebrated as the Raffaele of Flanders. De Vos, Segre, Diepenbech, Teniers, Jordaens, stand prominent in the catalogue of merit in the same school.

Rubens possessed a most fertile and extensive genius, and produced an immense number of works. This extraordinary painter distinguished himself equally in historical, portrait, and landscape painting; in animals, fruits, and flowers. He both invented and executed with the utmost facility. His drawing, although overcharged, is not without considerable merit. He had great knowledge of anatomy; but he was hurried away by the ardour of execution, and too often sacrificed form and correctness to splendour, and the magic charms of colour. He excelled in colouring, and chiaro-scuro. He studied principally in Lombardy, after the works of Titian, Paolo Veronese, and Tintoret, from whose excellences he formed rules for his own practice, from which he seldom deviated.

He was not only an eminent painter, but

an accomplished scholar, and rose to high employment in the service of his country, visiting several courts in the character of an ambassador.

Of the disciples of Rubens, Vandyck best comprehended all the rules and general maxims of his master; and even surpassed him in the delicacy of his colouring, particularly in portraits, in which he stands one of the highest masters of his art.

France. The French school or schools may be classed in three different æras, and characterized by as many different styles; two prior, and one modern, since the period of the late revolution. The artists of the former schools chiefly adopted the manners of the various painters whose works they studied or imitated. But Poussin, Vouet, Le Brun, and Le Sueur, are those masters who have given distinction to the French school in the province of history. The first and the last of these have been compared by the French to Raffaele, whose example Le Sueur in particular considered as his model. Poussin studied the antique statues with so great devotion, that his pictures frequently bear a strong resemblance to them. Le Brun's battles of Alexander are deservedly celebrated for their spirit, composition, and correct drawing. Gaspar Dughet (commonly called Gaspar Poussin, from his master's name, which he adopted), and Claude Gelée (called Claude Lorraine, from the place of his birth), are eminent examples of excellence in landscape. The latter appears to stand without a rival, or at least stood unrivalled in his time. Both these painters derived their professional knowledge, as well as their choice of subjects, from the fascinating and classic objects of imitation which they found in Italy, where they studied and flourished.

The arts which had been raised in France by the masters before-mentioned to very considerable dignity, sunk in the second school of Boucher and Vaulor to a state of imbecility and affectation. The reputation of a colourist was sought by exaggerated tints, and the hand of a master was conceived to consist in ostentatious penciling.

In a more recent period, and particularly since the revolution, a new style has been introduced into the arts. Vien was the first reformer of this class, and his example has been vigorously followed by David and his contemporaries. They have endeavoured to substitute a simple and rigid taste in the place of false and glittering manners. The attempt is laudable: the result will be judged of by posterity.

The comparative merits of those modern schools which have been hitherto mentioned, are thus given by Richardson:

"The painters of the Roman school were the best designers, and had a kind of greatness, but it was not antique. The Venetian and Lombard schools had excellent colourists and a certain grace, but entirely modern, especially those of Venice; but their drawing was generally incorrect, and their knowledge in history and the antique very little: and the Bolognese school is a sort of composition of the others. Even Annibale himself possessed not any part of painting in the perfection that is to be seen in those from whom his manner is composed; though, to make amends, he possessed more parts than perhaps any other master, and in a very high degree.

"The works of those of the German schools have a dryness and ungraceful stiffness not like what is seen amongst the old Florentines, that has something in it pleasing however; but this is odious, and as remote from the antique as Gothicism could carry it.

"The Flemings have been good colourists, and imitated nature as they conceived it; that is, instead of raising nature, they fell below it, though not so much as the Germans, nor in the same manner. Rubens himself lived and died a Fleming, though he would fain have been an Italian; but his imitators have caricatured his manner; that is, they have been more Rubens in his defects than he himself was, but without his excellences.

"The French, excepting some few of them (N. Poussin, Le Sueur, Sebastien Bourdon, &c.), as they have not the German stiffness, nor the Flemish ungracefulness, neither have they the Italian solidity; and in their airs of heads and manners, they are easily distinguished from the antique, how much soever they may have endeavoured to imitate it."

Spain. The art of painting began to flourish in Spain during the reigns of Charles the Fifth and Philip the Second. The style of painting, however, was not distinguished by great excellence until the works of Velasquez appeared. From the masterly imitation of nature displayed in his pictures, the school of the nation has been formed.

Zurbaran and Herrera are among the best painters before Velasquez; and Murillo for the most distinguished after him. The softness of tints and harmony of colour in the paintings of Murillo seem to enchant the eye.

In Russia the arts are at present cultivated with great energy, and with unremitting attention on the part of the government.

In America also, great establishments are forming at New York and Philadelphia, with the same view to the promotion of the arts.

It now only remains to speak of the art of painting in England, where it is at present making great advances towards excellence.

Painting has been cultivated in England at several periods with various success. We shall here give the account of it from Mr. West's letter in the third number of Academic Annals, published by the Royal Academy of London.

"Many sovereigns of this country have noticed and patronized the fine arts. Edward the Third caused several chapels to be embellished with painted glass and enamelled monuments, as well as with paintings on the walls, representing scriptural subjects, and others from the church legends, together with portraits of then existing characters of both sexes. The chapel of St. Stephen, Westminster, was the most conspicuous.

"Henry the Seventh gave patronage to many ingenious men, both in painting, sculpture, and architecture.

"Henry the Eighth followed the example of his father, in giving patronage to eminent men. He invited those of the greatest celebrity in painting in Italy, Germany, and Flanders, to visit his capital. Raffaele and Titian he wished to see at his court; and he endeavoured to draw them thither by the most splendid offers: but not succeeding in his desire, he procured several of their works; in particular the picture of St. George, by Raffaele, at present in the possession of the king of Spain, and the two pictures by Titian, now in the gallery of the marquis of Stafford; the subjects of which are, Diana and Acteon, and Diana and Calisto. He was more fortunate in his invitation to Holbein, at that time famous as a portrait painter, who resided in Henry's palace, and whose works were soon spread through the kingdom.

"Charles the First, more attached to the fine arts than any of his predecessors, formed a splendid collection of the works of the great Italian and Flemish masters. He invited to his court Rubens and Vandyck, and other painters of considerable eminence, from Flanders and Holland; and he gloried in counting among his natural subjects Inigo Jones, his architect, and Dobson, who rose to eminence in painting. These were the two first English artists who enjoyed the patronage of royal favour.

"Charles the Second was proud to follow the liberal example of his father, in bestowing rewards on ingenious artists. He patronized most of those who visited his court from Italy, Flanders, Germany, and Holland; of which the decorative paintings on the walls in Windsor-castle, and the palace of Hampton-court, by Verrio, and others, are evident proofs; beside many pictures from poetical subjects, by Gennari, as well as portraits by several painters of considerable eminence. The favours which this monarch showered on the arts, were, however, confined to foreign artists.

"Queen Anne was the first of our sovereigns who called into activity the British pencil, as the paintings in the cathedral of St. Paul's, and the hospital at Greenwich, by sir James Thornhill, and others under his direction, sufficiently evince. In architecture, sir Christopher Wren was equally distinguished by her favour.

"But to form the great epocha of patronage conferred by a British king on British subjects, in painting, sculpture, and architecture, was reserved for the reign of his present majesty, George the Third.

"In the year 1768, his majesty gave his royal sanction to a plan formed for the establishment of an academy of painting, sculpture, and architecture, of which he was graciously pleased to become the protector and patron.

"In the three branches of art which constitute that academy, he found many artists already formed: among others of considerable celebrity in painting, Reynolds, Wilson, Hayman, Gainsborough, Hoare, Danu, Mortimer, Barret, Sandby, Wright, Cotes, and West; in sculpture, Bacon, Nollekens, and Wilton; in architecture, Chambers, G. Dance, Stuart, T. Sandby, Gwyn, and the two Adams.

"At the same time, Strange, Woollett, Hall, Green, and Mac Ardell, shone with marked eminence among the engravers. The merits of our engravers, blended with the labours of the painter, opened a new avenue to fame. The harmonious softness of Strange; the united skill of Wilson and Woollett in landscape, as seen in the prints of Niobe, Phaeton, Ceyx, Celadon and Amelia, &c.;

the portraits in mezzotinto from sir Joshua Reynolds, by M'Ardell, Fisher, &c.; the successful combination of West with Earlom, Green, Woollett, Hall, &c. in historical works, as seen in the prints of Agrippina, Regulus, Hannibal, Wolfe, La Hogue, the Boyne, Penn, Cromwell, and the Restoration, &c. spread the celebrity of English works of art through the medium of engraving; and the circumstance of these prints rising to a higher price in every market throughout the continent than had ever been known in the annals of the arts, inspired those commercial views which afterwards produced the galleries of Shakspeare, under Boydell; the poets, under Macklin; historical, under Bowyer, &c. &c.; giving to this country a new source of commerce, highly beneficial to its interests, and unexampled in any other."

English school. To the list of painters mentioned by West, are to be added several who unfortunately experienced no royal patronage. Among these is Hogarth, whose unrivalled excellence in works of humour is principally known to us by the numerous engravings from his pictures.

Of the modern English school, sir Joshua Reynolds was the founder, and his works still remain its greatest glory. They not only give him the most distinguished rank among the artists of the present age, but the effects produced by them on the rising artists, as well as by the elevated principles inculcated in his discourses delivered at the Royal Academy, will secure his reputation as long as England shall pay respect to superior talents. The English taste appears to be formed on the great masters of the Italian and Flemish schools. Reynolds professed an admiration and preference of Michael Angelo, but his own works are in no point similar to that great master of design.

The names of Gainsborough and Wilson stand the highest in landscape painting.

The painters of this school have been distinguished as less rigid with regard to the forms and correctness of their drawing, than ambitious of striking and poignant effect. "Beauty," says the French Encyclopædia, "ought to be the characteristic of the English school, because the artists have it so frequently displayed before their eyes. If this beauty is not precisely similar to the antique, it is not inferior to it.

"The English school should also be distinguished for the truth of expression, because the liberty enjoyed in that country gives to every passion its natural and unbiassed operation."

The best accounts of painting and painters are to be found in the works of Lionardo da Vinci, Alberti, Lomazzo, and Bellori; and in the Lives of the Painters, by Vasari and Du Piles; Felibien's Entretiens sur les Vies des Peintres, and his other writings; the Discourses delivered by Reynolds in the Royal Academy of London; the various Treatises by Mengs; Richardson on Painting; and De Arte Graphicâ, by Du Fresnoy.

The later publications of Barry, Shee in his Rhymes on Art, and Howe in his Inquiry into the present State of the Arts in England, convey the most accurate information concerning the progress of painting in this country.

PAKFONG, or white copper, a metal composed of copper, nickel, and zinc. The zinc amounts to nearly one-half of the whole, and the proportions of copper and nickel are as 5 to 13. This compound metal is much used among the Chinese.

PALÆSTRA, in Grecian antiquity, a public building, where the youth exercised themselves in wrestling, running, playing at quoits, &c.

PALAMEDEA, a genus of birds belonging to the order of grallæ. The character of this genus is, the bill bends down at the point with a horn, or with a tuft of feathers erect near the base of it; the nostrils are oval; the toes are divided almost to their origin, with a small membrane between the bottoms of each.

There are two species; the first of which is the palamedea cornuta, or horned screamer. It is about the size of a turkey; in length about three feet four inches. The bill is two inches and a quarter long, and black; the upper mandible is a little gibbous at the base; the under shuts beneath it, as in the gallinaceous tribe: the nostrils are oval and pervious, and placed near the middle of the bill. From the crown of the head springs a slender horn of more than three inches in length, and pointed at the end: the irides are the colour of gold: the plumage on the head, neck, and upper part of the body, is black, margined with grey on the first, and downy: at the bend of the wing are two sharp horny spurs. The female, we are told, is very like the male.

It is remarked, that they are always met with in pairs; and if one dies, the other mourns to death for the loss. They frequent places near the water; make a large nest of mud, in the shape of an oven, upon the ground; and lay two eggs, the size of those of a goose. The young are brought up in the nest till able to shift for themselves. They have but one nest in the year, which is in January or February, except the first eggs are taken away, when they make a second in April or May. The young birds are frequently eaten by the natives, though the colour of the flesh is very dark; that of the old ones is tough and ill tasted. By some authors this species is said to feed on crabs and birds, such as pigeons, poultry, and even to attack sheep and goats; but this is denied by others, who say that its principal food is reptiles. The cornuta is a rare species. It is found in certain districts in Cayenne, Guiana, Surinam, and other parts of South America, chiefly in the marshes and wet savannas, and for the most part near the sea.

The second species of palamedea is the cristata, or crested screamer. This bird is about the size of a heron: the bill is short, bent like that of a bird of prey, and of a yellowish brown: the irides are gold-coloured: on the forehead, just above the bill, is a tuft of black feathers variegated with ash-colour: the head, neck, and body, are grey, mixed with rufous and brown, most inclining to the last on the wings and tail; the wings are not furnished with spurs; the legs pretty long, of a dull yellow; claws brown; the hind toe placed high up, so as not to touch the ground in walking. This bird inhabits Brazil.

PALATE. See Anatomy.

PALATINE COUNTIES, are those of Chester, Durham, and Lancaster. See Counties Palatine.

PALAVIA, a genus of the monadelphia polyandria class and order. The calyx is half five-cleft; style many-cleft; capsule many-seeded; cells in a ball on the central receptacle. There are two species, of no note.

PALE, in heraldry, one of the honourable ordinaries of an escutcheon, being the representation of a pale or stake placed upright, and comprehending the whole height of the coat from the top of the chief to the point. See Heraldry.

PALISADE, or Palisado, in fortification, an inclosure of stakes or piles driven into the ground, each six or seven inches square, and eight feet long, three whereof are hid under ground. Palisadoes are generally used to fortify the avenues of open forts, gorges, half-moons, the bottoms of ditches, the parapets of covert-ways, and in general all posts liable to surprize, and to which the access is easy. Palisadoes are usually planted perpendicularly, though some make an angle inclining towards the ground next the enemy, that the ropes cast over to tear them up may slip.

Palisades, *Turning*, are an invention of M. Coehorn, in order to preserve the palisades of the parapet of the covert-way from the besieger's shot. He orders them so, that as many of them as stand in the length of a rod, or in about ten feet, turn up and down like traps, so as not to be in sight of the enemy till they just bring on their attack, and yet are always ready to do the proper service of palisades.

PALISSE, in heraldry, a bearing like a range of palisades before a fortification, represented on a fesse, rising up a considerable height, and pointed at top, with the field appearing between them.

PALLADIUM. In the month of April, 1803, it was announced by a public notice, that a new noble metal called palladium was sold at Mr. Forster's, Gerard-street, Soho, London. Some of its properties are mentioned in the paper, but the name of the discoverer is concealed. Mr. Chenevix, suspecting imposition from the unusual manner in which the discovery was announced, made some experiments on it to discover its composition, and soon found that its properties could not be referred to any known metal. This induced him to purchase all that remained in the hands of the vender. It was sold at the rate of 25 grains per guinea.

It had been worked by art, and was offered for sale in thin laminæ. When polished, it had exactly the appearance of platinum. The laminæ were very flexible. The specific gravity varied from 10.972 to 11.482.

The effects of galvanic electricity on it were the same as on gold and silver. When exposed to the blowpipe, the side farthest removed from the flame became blue. A very violent heat is necessary to melt it. The button, by fusion, lost a little of its weight, but its specific gravity was increased from 10.972 to 11.871. It was harder than iron, and appeared chrystallized. The fracture was fibrous.

When strongly heated, if it is touched with sulphur it melts, and continues melting till the compound ceases to be red-hot. The sulphuret is brittle, and whiter than palladium. It was not altered by charcoal. It united with the different metals, and formed alloys; the properties of which have been described by Mr. Chenevix.

When exposed to the action of melted potass, it loses its brilliancy, and a little of its weight. Soda acts with less violence. When ammonia is kept over it for some days, it acquires a blue colour.

Sulphuric acid, when boiled upon palladium, acquires a fine red colour, and dissolves a portion of it; but its action is not very powerful. Nitric acid acts with much greater energy, and oxydizes and dissolves it, forming a very beautiful red solution. Muriatic acid, when long boiled upon it, becomes of a beautiful red colour. Nitro-muriatic acid attacks it with great violence, and forms a fine red solution.

The alkalies and earths throw down a fine orange powder from these solutions; and when ammonia is used, the supernatant liquid is sometimes of a fine greenish blue. Sulphat, nitrat, and muriat of potass and of ammonia, throw down orange precipitates, as they do from the solutions of platinum. Muriat of tin throws down a dark orange or brown precipitate from neutralized salts of palladium. Sulphat of iron throws down palladium in the metallic state. Prussiat of potass occasions an olive-coloured precipitate, and water containing sulphureted hydrogen gas a dark brown one. Fluoric, arsenic, phosphoric, oxalic, tartaric, citric acids, and their salts, precipitate some of the solutions of palladium, and form various compounds with it.

Such are the properties of palladium ascertained by Mr. Chenevix. They indicate a substance different from every other known metallic body. Still he considered the substance as a compound, and tried various ways of forming one similar. At last he suspected mercury and platinum as likely to be its constituents; and after various trials, hit upon the following mode of forming it, which succeeded:

One hundred parts of platinum, previously purified by solution in nitro-muriatic acid, and precipitation by sal ammoniac, were dissolved in nitro-muriatic acid. To the solution 200 grains of red oxide of mercury were added. These not saturating the excess of acid, he continued to add more till the acid was saturated. A solution of sulphat of iron was put into a long-necked matrass; the mixed solution of platinum and mercury was poured into it, and the matrass heated on a sand bath. A copious precipitate soon fell, and the inside of the matrass was coated with a thin metallic crust. This crust, collected and washed, was put into a charcoal crucible, and exposed to a violent heat; a button of metal was obtained, which possessed the properties of palladium. From the proportions employed, Mr. Chenevix concluded, that palladium is composed of two parts of platinum, and one of mercury.

The extraordinary consequences that follow from this experiment will occur at once to the reader. Here is a compound of two metals, which cannot be decomposed by art. And if we know one such compound, why may not many of the other supposed metals be such compounds?

We have here a compound containing mercury, one of the most volatile substances in nature, in such a state as to resist the most violent heat without quitting its combination: so that one of the most apparently whimsical of all the alchymistical opinions is here verified.

But the specific gravity of palladium is one of the most extraordinary circumstances. It is considerably less than that of the lightest of its component parts. The specific gravity of platinum cannot be stated at less than 22. The specific gravity of mercury may be stated at 13.5; but the actual specific gravity was only 11.2. So that an expansion amounting to more than a third of the whole has taken place.

The experiments of Mr. Chenevix were repeated by some of the eminent chemists in London; among others, by Dr. Wollaston and Mr. Tennant: but these gentlemen could not succeed in obtaining palladium. Hence doubts are still entertained by some concerning the composition of this substance. But the well-known precision of Mr. Chenevix, and the uncertainty which he has himself pointed out of succeeding in a few trials, ought to induce us to give him full credit. Dr. Thompson tried the experiment with all the precautions he could think of to ensure success. The metallic crust announced by Mr. Chenevix was formed; and upon heating it violently in a charcoal crucible, a button was obtained of a white colour, and very like platinum. It was very porous, and therefore though malleable, it soon broke under the hammer. Its specific gravity was only 11.126. But this was partly owing to its porousness. It was acted upon by the three mineral acids; but the action of neither of them was violent, and the solution, instead of red, was a dirty reddish-brown. He could detect no iron by the usual tests; but the solutions gave unequivocal marks of the presence of platinum. In short, the button was not platinum, but at the same time it was not palladium.

PALASSIA, a genus of the syngenesia polygamia frustranea class and order. The receptacle is chaffy; down none; seeds vertical; margin ciliated; calyx imbricate. There is one species, a shrubby plant of Lima.

PALLET, in heraldry, is nothing but a small pale.

PALLET. See WATCH.

PALM, a measure of length, about three inches.

PALPITATION. See MEDICINE.

PALSY. See MEDICINE.

PALY, or PALE, in heraldry, is when the shield is divided into four or more equal parts, by perpendicular lines falling from the top to the bottom.

PANARY FERMENTATION. See FERMENTATION.

PANAX, GINSENG, a genus of the diœcia order, in the polygamia class of plants. In the umbel the corolla is five-petalled; stamina five; hermaphrodite calyx five-toothed; superior styles two; berry two-seeded; male calyx entire. There are nine species of this plant: 1. Quinquefolia. 2. Trifolia. 3. Fruticosa. 4. Arborea. 5. Spinosa. 6. Aculeata. 7. Chrysophylla. 8. Simplex. 9. Attenuata.

Ginseng was formerly supposed to grow only in Chinese Tartary, affecting mountainous situations, shaded by close woods: but it has now been long known that this plant is also a native of North America, whence M. Sarrasin transmitted specimens of it to Paris in the year 1704; and the ginseng since discovered in Canada, Pennsylvania, and Virginia, by Lafiteau, Kalm, Bartram, and others, has been found to correspond exactly with the Tartarian species; and its roots are now regularly purchased by the Chinese.

The dried root of ginseng, as imported here, is scarcely the thickness of the little finger, about three or four inches long, frequently forked, transversely wrinkled, of a horny texture, and both internally and externally of a yellowish-white colour. On the top are commonly one or more little knots, which are the remains of the stalks of the preceding years, and from the number of which the age of the root is judged of. "To the taste it discovers a mucilaginous sweetness, approaching to that of liquorice, accompanied with some degree of bitterness, and a slight aromatic warmth, with little or no smell. It is far sweeter, and of a more grateful smell, than the roots of fennel, to which it has by some been supposed similar; and differs likewise remarkably from those roots in the nature and pharmaceutic properties of its active principles, the sweet matter of the ginseng being preserved entire in the watery as well as the spirituous extract, whereas that of fennel-roots is destroyed or dissipated in the inspissation of the watery tincture. The slight aromatic impregnation of the ginseng is likewise in good measure retained in the watery extract, and perfectly in the spirituous."

The Chinese ascribe extraordinary virtues to the root of ginseng; and have long considered it as a sovereign remedy in almost all diseases to which they are liable; having no confidence in any medicine unless in combination with it. It is observed by Jartoux, that the most eminent physicians in China have written volumes on the medicinal powers of this plant. We know, however, of no proofs of the efficacy of ginseng in Europe; and from its sensible qualities, we judge it to possess very little power as a medicine.

PANCRATIUM, a genus of the hexandria monogynia class of plants, the flower of which consists of six lanceolated petals; its nectarium is twelve-cleft; stamina placed on the nectary. There are ten species, beautiful flowering plants, with large bulbs.

PANCREAS. See ANATOMY.

PANDANUS, a genus of the diœcia monandria class and order. There is no calyx or corolla; male anther sessile; female stigmas two; fruit compound. There is one species.

PANDECTS, in the civil law, collections made by Justinian's order, of five hundred and thirty-four decisions of the antient lawyers, on so many questions occurring in the civil law; to which that emperor gave the force and authority of law, by an epistle prefixed to them. The pandects consist of fifty books, and make the first part of the body of the civil law. See CIVIL LAW.

PANEL, in law. See JURY.

PANICUM, a genus of the digynia order, in the triandria class of plants. The calyx is trivalved, the third valvule being very small. The species are in number seventy-nine, grasses of different countries.

PANNEL, in law. See PANEL. In the

Scotch law, pannel signifies the prisoner at the bar, or person who takes his trial before the court of justiciary, for some crime.

Pannel, in joinery, is a tympanum, or square piece of thin wood, sometimes carved, framed, or grooved in a larger piece, between two upright pieces and two cross pieces.

Pannel, in masonry, is one of the faces of a hewn stone.

PANORPA, a genus of insects of the order neuroptera: the generic character is, snout horny, cylindric, with two feelers; stemmata three; antennæ longer than thorax; tail of the male chelated or clawed. The most familiar species of this genus is the panorpa communis of Linnæus, an insect very frequently seen in meadows during the early part of summer. It is a longish-bodied fly, of moderate size, with four transparent wings elegantly variegated with deep-brown spots: the tail of the mail insect, which is generally carried in an upright position, is furnished with a forceps, somewhat in the manner of a lobster's claw.

The panorpa coa is a native of Greece and the islands of the Archipelago, and is an insect of a very peculiar appearance. It is considerably larger than the preceding, and is distinguished by having the lower wings so extremely narrow or slender as to resemble a pair of linear processes with an oval dilatation at the tip, while the upper wings are very large, oval, transparent, and beautifully variegated with yellowish-brown bars and spots. See Plate Nat. Hist. fig. 340.

PANTHER. See Felis.

PAPAVER, the *poppy*, a genus of the monogynia order, in the polyandria class of plants, and in the natural method ranking under the 27th order, rhœadæ. The corolla is tetrapetalous; the calyx diphyllous; the capsule bilocular, opening at the pores below a persisting stigma. There are nine species: 1. The somniferum, or somniferous common garden-poppy. There are of this a great many varieties, some of them extremely beautiful. The white officinal poppy is one of the varieties of this sort. It grows often to the height of five or six feet, having large flowers, both single and double, succeeded by capsules or heads as large as oranges, each containing about 8000 seeds.

We are told, that in the province of Bahar in the East Indies, the poppy-seeds are sown in the months of October and November, at about eight inches distance, and well watered till the plants are about half a foot high; when a compost of dung, nitrous earth, and ashes, is spread over the areas; and a little before the flowers appear, they are again watered profusely till the capsules are half grown, at which time the opium is collected, for when fully ripe they yield but little juice: two longitudinal incisions from below upwards, without penetrating the cavity, are made at sun-set for three or four successive evenings; in the morning the juice is scraped off with an iron scoop, and worked in an iron pot in the sun's heat, till it is of a consistence to be formed into thick cakes of about four pounds weight; these are covered over with the leaves of poppy, tobacco, or some other vegetable, to prevent their sticking together, and in this situation they are dried. See Narcotic Principle.

2. The rhæas, or wild globular-headed poppy, rises with an upright, hairy, multiflorous stalk, terminated by many red and other-coloured flowers in the varieties, succeeded by globular smooth capsules. This plant is common in corn-fields, and flowers in June and July. The capsules of this species, like those of the somniferum, contain a milky juice of a narcotic quality, but the quantity is very inconsiderable, and has not been applied to any medical purpose; but an extract prepared from them has been successfully employed as a sedative. The flowers have somewhat of the smell of opium, and a mucilaginous taste, accompanied with a slight degree of bitterness. A syrup of these flowers is directed in the London Pharmacopœia, which has been thought useful as an anodyne and pectoral, and is therefore prescribed in coughs and catarrhal affections; but it seems valued rather for the beauty of its colour than for its virtues as a medicine.

3. The cambricum, or Welsh poppy, has a perennial root, pinnated cut leaves, smooth, upright, multiflorous stalks, a foot and a half high, terminated by many large yellow flowers, succeeded by smooth capsules.

4. The orientalis, or oriental poppy, has a large, thick, perennial root; long, pinnated, sawed leaves; upright, rough, uniflorous stalks, terminated by one deep-red flower, succeeded by oval smooth capsules. The flowers appear in May.

PAPER, sheets of a thin matter, made of some vegetable substance.

Paper-Making. Under this word we cannot do better than by giving a concise view of the art of making paper.

The first instrument is called the duster, made in the form of a cylinder, four feet in diameter, and five feet in length. It is altogether covered with a wire net, and put in motion by its connection with some part of the machinery. A convenient quantity of rags before the selection are inclosed in the duster, and the rapidity of its motion separates the dust from them, and forces it through the wire. It is of considerable advantage to use the duster before selection, as it makes that operation less pernicious to the selectors.

The selection is then to be made; and it is found more convenient to have the tables for cutting off the knots and stitching, and for forming them into a proper shape, in the same place with the cutting-table. The surface both of these and of the cutting-table is composed of a wire net, which in every part of the operation allows the remaining dust and refuse of every kind to escape.

The rags, without any kind of putrefaction, are again carried from the cutting-table back to the duster, and from thence to an engine, where, in general, they are in the space of six hours reduced to the stuff proper for making paper. The hard and soft of the same quality are placed in different lots; but they can be reduced to stuff at the same time, provided the soft is put somewhat later into the engine.

The engine is that part of the mill which performs the whole action of reducing the rags to paste, or, as it may be termed, of trituration. The number of the engines depends on the extent of the paper-work, on the force of water, or on the construction of the machinery.

When the stuff is brought to perfection, it is conveyed into a general repository, which supplies the vat from which the sheets of paper are formed. This vat is made of wood; and generally about five feet in diameter, and two and a half in depth. It is kept in temperature by means of a grate introduced by a hole, and surrounded on the inside of the vat with a case of copper. For fuel to this grate, they use charcoal or wood; and frequently, to prevent smoke, the wall of the building comes in contact with one part of the vat, and the fire has no communication with the place where they make the paper.

Every vat is furnished on the upper part with planks inclosed inwards, and even railed in with wood, to prevent any of the stuff from running over in the operation. Across the vat is a plank which they call the trepan, pierced with holes at one of the extremities, and resting on the planks which surround the vat.

The forms or moulds are composed of wire cloth, and a moveable frame. It is with these that they fetch up the stuff from the vat, in order to form the sheets of paper. The sides of the form are made of oak, which is previously steeped in water, and otherwise prepared to prevent warping. The wire cloth is made larger than the sheet of paper, and the excess of it on all sides is covered with a moveable frame. This frame is necessary to retain the stuff of which the paper is made on the cloth; and it must be exactly adapted to the form, otherwise the edges of the paper will be ragged and badly finished. The wire cloth of the form is varied in proportion to the fineness of the paper and the nature of the stuff.

The felts are pieces of woollen cloth spread over every sheet of paper, and upon which the sheets are laid to detach them from the form, to prevent them from adhering together, to imbibe part of the water with which the stuff is charged, and to transmit the whole of it when placed under the action of the press. The two sides of the felt are differently raised: that of which the hair is longest is applied to the sheets which are laid down; and any alteration of this disposition would produce a change in the texture of the paper. The stuff of which the felts are made should be sufficiently strong, in order that it may be stretched exactly on the sheets without forming into folds; and, at the same time, sufficiently pliant to yield in every direction without injury to the wet paper. As the felts have to resist the reiterated efforts of the press, it appears necessary that the warp be very strong, of combed wool, and well twisted. On the other hand, as they have to imbibe a certain quantity of water, and to return it, it is necessary that the woof be of carded wool, and drawn out into a slack thread. These are the utensils, together with the press, which are used in the apartment where the sheets of paper are formed.

The vat being furnished with a sufficient quantity of stuff and of water, two instruments are employed to mix them; the one of which is a simple pole, and the other a pole armed with a piece of board, rounded and full of holes. This operation is repeated as often as the stuff falls to the bottom. In the principal writing-mills in England, they use for this purpose what is called a hog; which is a machine within the vat, that, by means of a small wheel on the outside, is made to turn constantly round, and keep the stuff in perpetual motion. When the stuff and water are properly mixed, it is easy to perceive whether the previous operations have been complete. When the stuff floats close, and in regular flakes, it is a proof that it has been well triturated; and the parts of the rags which have escaped the rollers also appear.

After this operation the workman takes one of the forms, furnished with its frame, by the middle of the short sides; and fixing the frame round the wire cloth with his thumbs, he plunges it obliquely four or five inches into the vat, beginning by the long side, which is nearest to him. After the immersion he raises it to a level: by these movements he fetches up on the form a sufficient quantity of stuff; and as soon as the form is raised, the water escapes through the wire cloth, and the superfluity of the stuff over the sides of the frame. The fibrous parts of the stuff arrange themselves regularly on the wire-cloth of the form, not only in proportion as the water escapes, but also as the workman favours this effect by gently shaking the form. Afterwards, having placed the form on a piece of board, the workman takes off the frame or deckle, and glides this form towards the coucher; who, having previously laid his felt, places it with his left hand in an inclined situation, on a plank fixed on the edge of the vat, and full of holes. During this operation the workman applies his frame, and begins a second sheet. The coucher seizes this instant, takes with his left hand the form, now sufficiently dry, and, having laid the sheet of paper upon the felt, returns the form by gliding it along the trepan of the vat.

They proceed in this manner, laying alternately a sheet and a felt, till they have made six quires of paper, which is called a post: and this they do with such swiftness, that, in many sorts of paper, two men make upwards of twenty posts in a day. When the last sheet of the post is covered with the last felt, the workmen about the vat unite together, and submit the whole heap to the action of the press. They begin at first to press it with a middling lever, and afterwards with a lever about fifteen feet in length. After this operation, another person separates the sheets of paper from the felts, laying them in a heap; and several of these heaps collected together are again put under the press.

The stuff which forms a sheet of paper is received, as we have already said, on a form made of wire cloth, which is more or less fine in proportion to the stuff, and surrounded with a wooden frame, and supported in the middle by many cross bars of wood. In consequence of this construction, it is easy to perceive, that the sheet of paper will take and preserve the impressions of all the pieces which compose the form, and of the empty spaces between them.

The traces of the wire cloth are evidently perceived on the side of the sheet which was attached to the form, and on the opposite side they form an assemblage of parallel and rounded risings. As in the paper which is most highly finished, the regularity of these impressions is still visible, it is evident that all the operations to which it is submitted have chiefly in view to soften these impressions without destroying them. It is of consequence, therefore, to attend to the combination of labour which operates on these impressions. The coucher, in turning the form on the felt, flattens a little the rounded eminences which are in relievo on one of the surfaces, and occasions at the same time the hollow places made by the wire cloth to be partly filled up. Meanwhile, the effort which is made in detaching the form, produces an infinite number of small hairs on every protuberant part of the sheet.

Under the action of the press, first with the felts and then without them, the perfecting of the grain of paper still goes on. The vestiges of the protuberances made by the wires are altogether flattened, and of consequence the hollows opposite to them disappear also; but the traces formed by the interstices of the wire, in consequence of their thickness, appear on both sides, and are rounded by the press.

The risings traced on each side of the paper, and which can be discovered by the eye on that which is most highly finished, form what is called the grain of paper. The different operations ought to soften, but not destroy it; which is effectually done by employing the hammer. This grain appears in the Dutch paper; which is a sufficient proof that though they have brought this part of the art to the greatest perfection, they have not employed hammers, but more simple and ingenious means. The grain of paper is often disfigured by the felts when they are too much used, or when the wool does not cover the thread. In this case, when the paper is submitted to the press, it takes the additional traces of the warp and the woof, and composes a surface extremely irregular.

The paper the grain of which is highly softened, is much fitter for the purposes of writing than that which is smoothed by the hammer: on the other hand, a coarse and unequal grain very much opposes the movements of the pen; as that which is beat renders them very uncertain. The art of making paper, therefore, should consist in preserving, and at the same time in highly softening, the grain: the Dutch have carried this to the highest perfection.

The exchange succeeds the operation last described. It is conducted in a hall contiguous to the vat, supplied with several presses, and with a long table. The workman arranges on this table the paper, newly fabricated, into heaps; each heap containing eight or ten of those last under the press, kept separate by a woollen felt. The press is large enough to receive two of them at once, placed the one at the other's side. When the compression is judged sufficient, the heaps of paper are carried back to the table, and the whole turned sheet by sheet, in such a manner that the surface of every sheet is exposed to a new one; and in this situation they are again brought under the press. It is in conducting these two operations sometimes to four or five times, or as often as the nature of the paper requires, that the perfection of the Dutch plan consists. If the stuff is fine, or the paper slender, the exchange is less frequently repeated. In this operation it is necessary to alter the situation of the heaps, with regard to one another, every time they are put under the press; and also, as the heaps are highest toward the middle, to place small pieces of felt at the extremities, in order to bring every part of them under an equal pressure. A single man with four or five presses may exchange all the paper produced by two vats, provided the previous pressing at the vats is well performed. The work of the exchange generally lasts about two days on a given quantity of paper.

When the paper has undergone these operations, it is not only softened in the surface, but better felted, and rendered more pliant in the interior parts of the stuff. In short, a great part of the water which it had imbibed in the operation of the vat is dissipated. By the felting of paper is understood the approximation of the fibres of the stuff, and their adhering more closely together. The paper is felted in proportion as the water escapes, and this effect is produced by the management and reiterated action of the press. Was it not for the gradual operation of the press, the paper would be porous, and composed of filaments adhering closely together. The superiority of the Dutch over the French paper, depends almost entirely on this operation.

If the sheets of paper are found to adhere together, it is a proof that the business of the press has been badly conducted. To avoid this inconveniency, it is necessary to bring down the press at first gently, and by degrees with greater force, and to raise it as suddenly as possible. By this means the water, which is impelled to the sides of the heaps, and which has not yet escaped, returns to the centre; the sheets are equally dry, and the operation is executed without difficulty.

According to the state of dryness in which the paper is found when it comes from the apartment of the vat, it is either pressed before or after the first exchange. The operation of the press should be reiterated, and managed with great care; otherwise, in the soft state of the paper, there is a danger that its grain and transparency are totally destroyed. Another essential principle to the success of the exchange is, that the grain of the paper is originally well raised. For this purpose the wire cloth of the Dutch forms is is composed of a rounder wire than that used in France, by which they gain the greatest degree of transparency, and are in no danger of destroying the grain. Besides this, the Dutch take care to proportion the wires even where the forms are equal to the thickness of the paper.

Almost every kind of paper is considerably improved by the exchange, and receives a degree of perfection which renders it more agreeable in the use. But it is necessary to observe at the same time, that all papers are not equally susceptible of this melioration; on the contrary, if the stuff is unequal, dry, or weakened by the destruction of the fine parts, it acquires nothing of that lustre and softness, and appearance of velvet, which the exchange gives to stuff properly prepared.

The sheds for drying the paper are in the neighbourhood of the paper-mill, and are furnished with a vast number of cords, on which they hang the sheets both before and after the sizing. The sheds are surrounded with moveable lattices, to admit a quantity of air sufficient for drying the paper. The cords of the shed are stretched as much as possible; and the paper, four or five sheets of it together, is placed on them by means of a wooden instrument resembling a pick-axe. The principal difficulty in drying the paper consists in gradually admitting the external air, and in preventing the cords from imbibing moisture. With regard to the first of these, the Dutch use very low sheds, and construct their lattices with great exactness. By this means the Dutch paper is dried equally, and is extremely supple before the sizing. They prevent the cords from imbibing the water by covering them with wax. In using such cords, the moisture does not continue in the line of contact between the paper and the cord, which prevents the sheet from stretching in that particular place by its weight, and from the folds which the moisture in the subsequent operations might occasion. The Dutch also employ cords of considerable thickness, and place fewer of them under the sheets; by which means they diminish the points of contact, and give a freer and more equal circulation to the air.

The size for paper is made of the shreds and parings got from tanners, curriers, and parchment-makers. All the putrefied parts and the lime are carefully separated from them, and they are inclosed into a kind of basket, and let down by a rope and pulley into the cauldron. This is a late invention, and serves two valuable purposes. It makes it easy to draw out the pieces of leather when the size is extracted from them by boiling, or easy to return them into the boiler if the operation is not complete. When the substance is sufficiently extracted, it is allowed to settle for some time; and it is twice filtred before it is put into the vessel into which they dip the paper.

Immediately before the operation, a certain quantity of alum is added to the size. The workman takes a handful of the sheets, smoothed and rendered as supple as possible, in his left hand, dips them into the vessel, and holds them separate with his right, that they may equally imbibe the size. After holding them above the vessel for a short space of time, he seizes on the other side with his right hand, and again dips them into the vessel. When he has finished ten or a dozen of these handfuls, they are submitted to the action of the press. The superfluous size is carried back to the vessel by means of a small pipe. The vessel in which the paper is sized is made of copper, and furnished with a grate, to give the size when necessary a due temperature; and a piece of thin board or felt is placed between every handful as they are laid on the table of the press.

The Dutch are very careful in sizing their paper, to have every sheet in the same handful of equal dryness; because it is found that the dry sheets imbibe the size more slowly than those which retain some degree of moisture. They begin by selecting the padges in the drying-house; and after having made them supple, and having destroyed the adherence between the sheets, they separate them into handfuls in proportion to the dryness, each of them containing that number which they can dip at one time. Besides this precaution, they take care to apply two sheets of brown paper of an equal size to every handful. This brown paper, firm, solid, and already sized, is of use to support the sheets.

As soon as the paper is sized, it is the practice at some paper-mills to carry it immediately to the drying-house, and hang it before it cools, sheet by sheet, on the cords. The paper, unless particular attention is paid to the lattices of the drying-house, is apt to dry too fast, whereby a great part of the size goes off in evaporation; or, if too slow, it falls to the ground. The Dutch drying-houses are the best to prevent these inconveniences: but the exchange after the sizing, which is generally practised in Holland, is the best remedy. They begin this operation on the handfuls of paper, either while they are still hot, or otherwise as they find it convenient. But, after the exchange, they are careful to allow the heaps to be altogether cold before they are submitted to the press. Without this precaution, the size would either be wholly squeezed out by the press of the exchange, or the surface of the paper become very irregular. It is of consequence that the paper, still warm from the sizing, grows gradually firm, under the operation of the exchange, in proportion as it cools. By this method it receives that varnish which is afterwards brought to perfection under the press, and in which the excellence of the paper either for writing or drawing chiefly consists. It is in consequence of the exchanging and pressing that the Dutch paper is soft and equal; and that the size penetrates into the body of it, and is extended equally over its surface.

The exchange after the sizing ought to be conducted with the greatest skill and attention, because the grain of the paper then receives impressions which can never be eradicated. When the sized paper is also exchanged, it is possible to hang more sheets together on the cords of the drying-house. The paper dries better in this condition, and the size is preserved without any sensible waste, because the sheets of paper mutually prevent the rapid operation of the external air. And as the size has already penetrated into the paper, and is fixed on the surface, the insensible progress of a well-conducted drying-house renders all the good effects more perfect in proportion as it is slowly dried.

If to these considerations is added the damage done to the paper in drying it immediately after the press of the sizing-room, whether it is done in raising the hairs by separating the sheets, or in cracking the surface, it is evident that the trouble of the second exchange is infinitely overpaid by the advantage.

When the paper is sufficiently dry, it is carried to the finishing-room, where it is pressed, selected, examined, folded, made up into quires, and finally into reams. It is here put twice under the press; first, when it is at its full size, and secondly, after it is folded.

The principal labour of this place consists in assorting the paper into different lots, according to its quality and faults; after which it is made up into quires. The person who does this must possess great skill, and be capable of great attention, because he acts as a check on those who separated the paper into different lots. He takes the sheets with his right hand, folds them, examines them, lays them over his left arm till he has the number requisite for a quire, brings the sides parallel to one another, and places them in heaps under the table. An expert workman, if proper care has been taken in assorting the lots, will finish in this manner near 6000 quires in a day.

The paper is afterwards collected into reams of 20 quires each, and for the last time put under the press, where it is continued for 10 or 12 hours, or as long as the demand of the paper-mill permits. We shall explain the structure of one of the best paper-mills now in use.

Plate Paper Mill, &c. figs. 1, 2, 3, explains the construction of an engine paper-mill. ABDE, fig 3, is a large vat of wood, lined with lead; on each side of it are bolted two pieces of wood, F,G; the piece E has a strong lever H jointed to it; the other end of this lever enters a mortise in the piece F, and has a screw fastened to it, which comes up through the top of the piece, where a nut *a* is put on it, by turning which the lever can be raised or lowered at pleasure. In the middle of each of the levers HH, is fixed a brass socket, in which the spindle of the cylinder I lies; and on the outer end of this spindle is fixed a pinion K, working into other cog wheels, connecting with the water-wheel, steam-engine, &c. which gives it motion. The cylinder is made of wood, and has a great number of steel cutters fixed into it, parallel to the axis. These cutters act against a similar set fixed into a block of wood L, fig. 2; this block goes through a hole in the side of the vat, and is kept in tight by a wedge, so that when the wedge is knocked out, the block can be taken out to sharpen the cutters: the ends of the cylinder work very close between the side of the vat, and a partition N in the middle of the vat, so that none of the rags can get through between them: the bottom of the vat is raised up at M, fig. 3. to the same lever with the axis of the cylinder, goes as near to its circumference as possible without touching, and then suddenly falls down to the block L. At the back of the vat a small leaden cistern O connects with it; through a hair sieve P is a crooked pipe, which brings clean water to the vat; the end of this pipe has a flannel bag tied over it, to catch any impurities which may be in the water.

Fig. 1. is a box which is put over the cylinder, and rests upon the edge of the vat, and the partition N; at each edge of this box is fixed a trough *bd*; when the box is put in its place, these connect with the top of the leaden pipes *ef*, fig. 3. on the side of the vat: on the edge of these troughs hair sieves *gg* are fixed; and before these boards, one of which is shewn at *h*, are slid in grooves in the sides of the box. The operation of the machine is as follows: The vat is filled with clean water, the box fig. 2. is put over the cylinder, and a quantity of rags is put into the vat. The cylinder being turned round with a velocity of 120 revolutions per minute in the direction of the arrow in fig. 2. draws the rags in between the cutters in the cylinder and the block L, and tears them to pieces; from the cylinder they go forwards into the vat, and turn slowly round in it till they come under the cylinder again. The great velocity of the cylinder throws the rags and water up against the sieves *g* in the box fig. 1.; the foul water runs through the sieve into the trough *bd*, and from thence into the pipes (*ef*), which convey it away, and the clean water is brought to the vat by the pipe P; when the foul water is wanted to be kept in

the boards are slid down before the sieve, as at *h*, fig. 1. which prevents the water going through the sieves. In larger mills two different engines are used; that into which the rags are first put is like fig. 3; the other one which is used to finish the rags is similar to it, but has much finer cutters, and the cylinder is let down much nearer the block L by the screw *a*.

The lower compartment of Plate Paper-making, represents one of the tables used in the manufactories in and near London, for printing the paper used for the hangings of rooms. A, is a square water-tight box, called the sieve, mounted upon legs; this box is about ¼ filled with water, mixed with paper-shavings, &c. and then another box B is put into it, so that it floats on the water; the bottom of this box is of parchment, and a frame covered with a piece of felt is laid upon it; the table D, where the printing is performed, has two pieces of wood *a* fixed upright in it; these have notches in them to receive the ends of a brass wire, which is put through the middle of the roll of paper *d*; the paper from this roll goes over the edge of the table, and is laid upon a horse, fig. 5. which has a roller on its top for the paper to lie on. On one part of the horse a number of small sticks *e*, a little longer than the width of the paper, are laid. The operation is conducted as follows: the workman takes a roll of paper (each of which is 12 yards long, and 22 inches wide) from the shelf F, under the table, and puts a brass wire through it, and lays its ends in the pieces *a*, as shewn in the figure 4.; he then pulls the end of the paper to the end of the table. In the mean time a boy, called the tier boy, who stands on the stool E, brushes the felt which lies in the sieve B over with the colour used in the printing; the workman then takes up the block (in which the device to be printed is cut as in wood cuts), by putting his hand through the strap nailed to the back of it, and presses its face upon the felt in the colour-sieve B: the water which is under causes the felt to touch the block in every part, and take colour equally over the surface of the block: he then removes the block, and lays it upon the paper near the end of the table; and takes up a mallet with a leaden head, called the mall, which has a small shelf *h*, in his right hand, and gives the block two blows on the back of it, to make the impression. He then puts down the mall, and lifts up the block (which his left hand never quitted), and turns round to take colour at the sieve: as he turns round to bring the block over the paper again, he takes hold of the edge of the paper with his right hand, and pulls it forward the proper distance to print again; in laying the block down, he guides it to its place with his right hand, and when it is laid he takes up the mall as before. In this manner he proceeds till the end of the paper touches the ground; the tier boy then goes and puts it over the horse, fig. 5. and returns to the sieve. When the middle of the paper nearly touches the ground, he goes again to the end of the paper, and pulls it straight over the horse, and lays it on the ground as in the figure. This operation he repeats as often as is necessary, till the pieces are finished: he then takes the poll, fig. 6. from the ground, and puts one of the sticks *e*, fig. 5. into the groove across its top. He then puts the paper on the sticks, and lifts them all together to the ceiling of the room, where he lodges the ends of the sticks upon a rack made for the purpose: he then takes down the pole, and puts up another stick in a different part, so as to hang up all the pieces in two or three loops to dry. In those prints which are very full, or in which there is much colour to lay on, the mall is not sufficient to give the impression: a lever is then used instead. Two of the legs of the table MN project some inches above it; between these, two bars P are bolted, the middle of which is strengthened by an upright post Q, whose end is fastened to the ceiling. The shelf *h* has a piece *m* put into it; the workman takes his colour, and places the block on the paper as before; but instead of taking the mall from the shelf *h*, he places the middle of the lever (the end of which was under the bar P, and the middle resting on the piece *m*) over the block, and presses his weight upon the outer end of the lever, which gives the impression: he then lifts up the lever, slides his right hand to the middle of it (keeping his left at the outer end), and returns the lever on to the piece *m*, then lifts up the block to take colour as before.

Paper, *Marbled*. See Marbling.

Paper-Office, an office in which all the public writings, matters of state and council, proclamations, letters, intelligences, negotiations abroad, and generally all dispatches that pass through the offices of the secretaries of state, are lodged, by way of library.

Paper-Office is also an office belonging to the court of king's bench.

PAPIER MACHE', is a substance made of cuttings of white or brown paper, boiled in water, and beaten in a mortar till they are reduced into a kind of paste; and then boiled with a solution of gum arabic or of size, to give tenacity to the paste, which is afterwards formed into different toys, &c. by pressing it into oiled moulds. When dry, it is covered with a mixture of size and lamp-black, and afterwards varnished.

PAPILIO, *butterfly*, a genus of insects of the order lepidoptera. The generic character is, antennæ thickening towards the extremity, commonly terminating in a knob or clavated tip; wings (when sitting) erect, and meeting upwards; flight diurnal.

The prodigious number of species, amounting to many hundreds, in this genus, renders it absolutely necessary to divide the whole into sections or sets, instituted from the habit or general appearance, and, in some degree, from the distribution of the colour on the wings. This division of the genus is conducted by Linnæus in a peculiarly elegant and instructive manner, being an attempt to combine, in some degree, natural and civil history, by attaching the memory of some illustrious antient name to an insect of a certain particular cast.

The first Linnæan division consists of the equites, distinguished by the shape of their upper wings, which are longer, if measured from their hinder angle to their anterior extremity, than from the same point to the base. Some of this division have filiform or sharpened antennæ, in which particular they resemble moths, but may generally be very clearly distinguished by their habit or general shape. The equites are either Troes (or Trojans), distinguished by having red or blood-coloured spots or patches on each side their breasts; or Achivi, Greeks, without red marks on the breast, of gayer colours in general than the former, and often having an eye-shaped spot at the inner corner of the lower wings.

The next division consists of the Heliconii. These are distinguished by the narrowness of their wings, which are also, in general, of a more transparent appearance than in the other divisions; their upper wings are also generally much more oblong than the lower, which are short in proportion.

The third division consists of the Danai, (from the sons and daughters of Danaus.) They are divided into danai candidi, or those in which the ground-colour of the wings is generally white; and the danai festivi, in which the ground-colour is never white, and in which a greater variety of colour occurs than in the candidi. The wings of the danai are of a somewhat rounder shape than those of the heliconii, or less stretched out.

The fourth section consists of the nymphales, and is distinguished by the edges of the wings being scolloped or indented: it is subdivided into the nymphales gemmati, in which eye-shaped spots are seen either on all the wings, or on the upper or lower pair only; and into the nymphales phalerati, in which no ocellated spots are visible on the wings, but, in general, a great variety of colours.

The fifth section contains the plebeii. These are, in general, smaller than the preceding kinds of butterflies: and are subdivided into plebeii urbicolæ, or those in which the wings are marked by semitransparent spots; and plebeii rurales, in which the spots or patches have no transparency.

The larvæ of butterflies are universally and emphatically known by the name of caterpillars, and are extremely various in their forms and colours, some being smooth, others beset with simple or ramified spines, &c. and some, especially those belonging to the division equites, are observed to protrude from their front, when disturbed, a pair of short tentacula or feelers, somewhat analogous to those of a snail.

The papilionaceous insects in general, soon after their enlargement from the chrysalis, and commonly during their first flight, discharge some drops of a red-coloured fluid, more or less intense in different species. This circumstance, exclusive of its analogy to the same process of nature in other animals, is peculiarly worthy of attention from the explanation which it affords of a phenomenon sometimes considered, both in antient and modern times, in the light of a prodigy; viz. the descent of red drops from the air; which has been called a shower of blood: an event recorded by several writers among the prodigies which took place after the death of the great dictator.

Among the equites troes, the papilio priamus should take the lead, not only from the corresponding dignity of the name, but from the exquisite appearance of the animal itself, which Linnæus considered as the most beautiful of the whole papilionaceous tribe.

This admirable species measures more than six inches from wing's end to wing's end: the upper wings are velvet-black, with a broad band of the most beautiful grass-green, and of a satiny lustre, drawn from the shoulder to the tip; and another on the lower part of the wing, following the shape of that part, and of a somewhat undulating appearance as it approaches the tip: the lower wings are of the same green colour, edged with velvet-black, and marked by four spots of that colour; while at the upper part of each, or at the part where the upper wings lap over, is a squarish orange-coloured spot: the thorax is black, with sprinklings of lucid green in the middle, and the abdomen is of a bright yellow, or gold-colour. On the under side of the animal the distribution of colours is somewhat different, the green being disposed in central patches on the upper wings, and the lower being marked by more numerous black as well as orange spots. The red or bloody spots on each side the thorax are not always to be seen on this the Trojan monarch. The papilio priamus is a very rare insect, and is a native of the island of Amboyna.

P. hector is very happily named, being of a deep or velvet-black colour, with the lower wings marked by numerous blood-red spots: the thorax is red on each side, and the upper wings have a pair of obscure, broken, whitish, transverse clouds or bars. It is a native of the East Indies. See Plate Nat. Hist. fig. 313.

Among the equites achivi, the P. menelaus may be considered as one of the most splendidly beautiful of the butterfly tribe. Its size is large, measuring, when expanded, about six inches; and its colour is the most brilliant silver-blue that imagination can conceive: changing, according to the variation of the light, into a deeper blue, and in some lights to a greenish cast: on the under side it is entirely brown, with numerous deeper and lighter undulations, and three large ocellated spots on each wing. It is a native of South America.

The P. machaon is an insect of great beauty, and may be considered as the only British species of papilio belonging to the tribe of equites.* It is commonly known among the English collectors by the title of the swallow-tailed butterfly, and is of a beautiful yellow, with black spots or patches along the upper edge of the superior wings: all the wings are bordered with a deep edging of black, decorated by a double row of crescent-shaped spots, of which the upper row is blue, and the lower yellow: the under wings are tailed, and are marked at the inner angle or tip with a round red spot bordered with blue and black. The caterpillar of this species feeds principally on fennel and other umbelliferous plants, and is sometimes found on rue. It is of a green colour, encircled with numerous black bands spotted with red, and is furnished on the top of the head with a pair of short tentacula of a red colour, which it occasionally protrudes from that part. In the month of July it changes into a yellowish-grey angular chrysalis, affixed to some convenient part of the plant, or other neighbouring substance, and from this chrysalis in the month of August proceeds the complete insect.

Of the division called heliconii the beautiful insect the papilio apollo is an example. It is a native of many parts of Europe, but has not yet been observed in our own country, and is somewhat larger than the common great cabbage-butterfly; of a white colour, with a slight semitransparency towards the tips of the wings, which are decorated with velvet-black spots; and on each of the lower wings are two most beautiful ocellated spots, consisting of a carmine-coloured circle with a white centre and black exterior border.

Of the division entitled danai candidi, the common large white butterfly, or P. brassica, is a familiar example: this insect is too well known to require particular description, and it may be only necessary to remind the reader that it proceeds from a yellowish caterpillar, freckled with blueish and black spots, and which changes during the autumn into a yellowish-grey chrysalis, affixed in a perpendicular direction to some wall, tree, or other object, some filaments being drawn across the thorax in order the more conveniently to secure its position. The fly appears in May and June, and is seen through all the summer.

Of the danai festivi the P. midamus may serve as an example; an elegant Asiatic species, of a black colour, with a varying blue lustre towards the tips of the upper wings, which are marked by many white spots, while the lower pair are streaked longitudinally with numerous white lines, and edged with a row of white specks.

Among the nymphales gemmati few can exceed in elegance the P. io, or peacock butterfly, a species by no means uncommon in our own country: the ground-colour of this insect is orange-brown, with black bars separated by yellow intermediate spaces on the upper edge of the superior wings, while at the tip of each is a most beautiful large eye-shaped spot, formed by a combination of black, brown, and blue, with the addition of whitish specks: on each of the lower wings is a still larger eye-shaped spot, consisting of a black central patch, varied with blue, and surrounded by a zone of pale brown, which is itself deeply bordered with black: all the wings are scolloped or denticulated. The caterpillar is black, with numerous white spots, and black ramified spines: it feeds principally on the nettle, changing to chrysalis in July, and the fly appearing in August.

P. jurtina is a species equally common, though far less beautiful. It is chiefly observed in meadows, and is of a brown colour, the upper wings having a much brighter or orange-ferruginous bar towards the tips, with a small, black, eye-shaped spot with a white centre: on the opposite or under side of the insect the same distribution of colours takes place.

Of the nymphales phalerati, few can surpass the common English species called P. atalanta, or the admirable butterfly: it is of the most intense velvet-black colour, with a rich carmine-coloured bar across the upper wings, which are spotted towards the tips with white; while the lower wings are black, with a deep border of carmine colour marked by a row of small black spots: the under surface of the wings also presents a most beautiful mixture of colours: the caterpillar is brown and spiny, feeds on nettles, and changes into a chrysalis in July, the fly appearing in August.

Of the last division, termed plebeii, may be adduced as an example a small English butterfly called P. malvæ, of a blackish or brown colour, with numerous whitish and semitransparent spots. It belongs to the plebeii urbicolæ.

To this division also belongs a very beautiful exotic species, a native of India, and of a most exquisite lucid blue colour, edged with black, and farther ornamented by having each of the lower wings tipped with two narrow black tail-shaped processes. It is the P. marsyas of Linnæus. See Plate Nat. Hist. figs. 311 and 313.

PAPISTS, persons professing the popish religion. By several statutes, if any English priest of the church of Rome, born in the dominions of the crown of England, came to England from beyond the seas, or tarried in England three days without conforming to the church, he was guilty of high treason; and they also incurred the guilt of high treason who were reconciled to the see of Rome, or procured others to be reconciled to it. By these laws also, papists were disabled from giving their children any education in their own religion. If they educated their children at home, for maintaining the schoolmaster, if he did not repair to church, or was not allowed by the bishop of the diocese, they were liable to forfeit 10*l.* a month, and the schoolmaster was liable to the forfeiture of 40*s.* a day: if they sent their children for education abroad, they were liable to forfeit 100*l.* and the children so sent were incapable of inheriting, purchasing, or enjoying, any lands, profits, goods, debts, legacies, or sums of money: saying mass was punishable by a forfeiture of 200 marks; and hearing it by a forfeiture of 100*l.*

But during the present reign the Roman Catholics have been in a great measure relieved from the restrictions formerly imposed on them. See 18 Geo. III. c. 60; and 31 Geo. III. c. 22.

PAPOPHORUM, a genus of the class and order triandria digynia. The calyx is two-valved, two-flowered; corolla two-valved, many-awned. There is one species, a grass of America.

PAPPUS, *down*. See BOTANY.

PAR, in commerce. See EXCHANGE.

PARABOLA, in geometry, a figure arising from the section of a cone, when cut by a plane parallel to one of its sides. See CONIC SECTIONS.

PARABOLIC CONOID, in geometry, a solid generated by the rotation of a parabola about its axis: its solidity is $= \frac{1}{2}$ of that of its circumscribing cylinder.

The circles conceived to be the elements of this figure, are in arithmetical proportion, decreasing towards the vertex.

A parabolic conoid is to a cylinder of the same base and height, as 1 to 2; and to a cone of the same base and height, as $1\frac{1}{2}$ to 1. See GAUGING.

PARABOLIC SPACE, the area contained between any entire ordinate and the curve of the incumbent parabola.

The parabolic space is to the rectangle of the semi-ordinate into the absciss, as 2 to 3; to a triangle inscribed on the ordinate as a base, it is as 4 to 3.

PARABOLOIDES, a name given to parabolas of the higher kind, which are algebraic curves.

PARACENTRIC MOTION, in astro-

* Unless we admit the papilio podalirius to be a British species also.

nomy, denotes so much as a revolving planet approaches nearer to, or recedes from, the sun, or centre of attraction.

PARADISE, *bird of*. See PARADISEA.

PARADISEA, in ornithology, a genus of birds belonging to the order of picæ. The beak is covered with a belt or collar of downy feathers at the base, and the feathers on the sides are very long.

"Birds of this genus (says Latham) have the bill slightly bending, the base covered with velvet-like feathers. The nostrils are small, and concealed by the feathers. The tail consists of ten feathers; the two middle ones, and sometimes more in several of the species, are very long, and webbed only at the base and tips. The legs and feet are very large and strong: they have three toes forward, one backward, and the middle connected to the outer one as far as the first joint. The whole of this genus have till lately been very imperfectly known; few cabinets possessing more than one species, viz. the greater, or what is called the common bird of Paradise; nor has any set of birds given rise to more fables, the various tales concerning which are to be found in every author; such as, their never touching the ground from their birth to death; living wholly on the dew; and being produced without legs. This last error is scarcely at this moment wholly eradicated. The circumstance which gave rise to it did not indeed at first proceed from an intention to deceive, but merely from accident. In the parts of the world which produce these birds, the natives made use of them as aigrets, and other ornaments of dress; and in course threw away the less brilliant parts. The whole trouble they were at on this occasion was merely to skin the bird, and, after pulling off the legs, coarser parts of the wings, &c. thrust a stick down the throat into the body, letting an inch or two hang out of the mouth, beyond the bill: on the bird's drying, the skin collapsed about the stick, which became fixed, and supported the whole. They had then no more to do than to put this end of it into a socket fitted to receive it, or fasten it in some manner to the turban, &c. By degrees these were imported into the other isles for the same uses, and afterwards were coveted by the Japanese, Chinese, and Persians, in whose countries they are frequently seen, as well as in many parts of India; the grandees of these last parts not only ornamenting themselves with these beautiful plumes, but adorning even their horses with the same."

Latham enumerates eight species, but suspects there may be more.

1. The largest bird of paradise is commonly two feet four inches in length; the head is small; the bill hard and long, of a pale colour. The head and back part of the neck are lemon-coloured, a little black about the eyes; about the neck the bird is of the brightest glossy emerald-green, soft like velvet, as is also the breast, which is black: the wings are large and chesnut-coloured: the back part of the body is covered with long, straight, narrow feathers, of a pale-brown colour, similar to the plumes of the ostrich. These feathers are spread when the bird is on the wing; for which reason he can keep very long in the air. On both sides of the belly are two tufts of stiff and shorter feathers, of a golden yellow, and shining. From the rump proceed two long stiff shafts, which are feathered on their extremities.

These birds are not found in Key, an island 50 Dutch miles east of Banda; but they are found at the Aroo islands, lying 15 Dutch miles farther east than Key, during the westerly or dry monsoon; and they return to New Guinea as soon as the easterly or wet monsoon sets in. They come always in a flock of 30 or 40, and are led by a bird which the inhabitants of Aroo call the king. This leader is black, with red spots; and constantly flies higher than the rest of the flock, which never forsake him, but settle when he settles; a circumstance that frequently proves their ruin when the king lights on the ground, whence they are not able to rise on account of the singular structure and disposition of their plumage. They are likewise unable to fly with the wind, which would ruin their loose plumage; but take their flight constantly against it, cautious not to venture out in hard-blowing weather, as a strong wind frequently obliges them to come to the ground. During their flight, they cry like starlings. Their note, however, approaches more to the croaking of ravens; which is heard very plainly when they are in distress from a fresh gale blowing on the back of their plumage. In Aroo, these birds settle on the highest trees, especially on the ficus benjamina of the hortus malabaricus, commonly called the waringa tree. The natives catch them with birdlime or in nooses, or shoot them with blunt arrows; but though some are still alive when they fall into their hands, the catchers kill them immediately, and sometimes cut the legs off; then they draw out the entrails, dry and fumigate the bodies with sulphur or smoke only, and sell them at Banda for half a rixdollar each; but at Aroo they may be bought for a spike-nail, or a piece of old iron. Flocks of these birds are often seen flying from one island to the other against the wind. In case they find the wind become too powerful, they fly straight up into the air, till they come to a place where it is less agitated, and then continue their flight. During the eastern monsoon, their tails are moulted, so that they have them only during four months of the western monsoon. See Plate Nat. Hist. fig. 315.

2. The smaller bird of Paradise is about 20 inches long. His beak is lead-coloured, and paler at the point. The eyes are small, and inclosed in black about the neck. The head and back of the neck are of a dirty yellow, the back of a greyish yellow, the breast and belly of a dusky colour, the wings small and chesnut-coloured. The long plumage is about a foot in length, and paler than in the large species; as in general the colours of this bird are less bright than the former. The two long feathers of the tail are constantly thrown away by the natives. This is in all respects like the greater sort; and they likewise follow a king or leader, who is, however, blacker, with a purplish cast, and finer in colour than the rest.

3 and 4. The large black bird of Paradise is brought without wings or legs for sale; so that no accurate description of it has yet been given. Its figure, when stuffed, is narrow and round, but stretched in length to the extent of four spans. The plumage on the head, neck, and belly, is black and velvet-like, with a hue of purple and gold, which appears very strong. The bill is blackish, and one inch in length. On both sides are two bunches of feathers, which have the appearance of wings, although they are very different, the wings being cut off by the natives. This plumage is soft, broad, similar to peacocks' feathers, with a greenish hue. Birds of this kind are brought only from one particular place of New Guinea. Besides the large black bird of Paradise, there is still another sort, whose plumage is equal in length, but thinner in body, black above, and without any remarkable gloss, not having those shining peacock-feathers which are found on the greater species. This wants likewise the three long-pointed feathers of the tail belonging to the larger black species.

5. The last species we shall mention is the king's bird. This creature is about seven inches long, and somewhat larger than a titmouse. Its head and eyes are small, the bill straight, the eyes included in circles of black plumage, the crown of the head is flame-coloured, the back of the neck blood-coloured, the neck and breast of a chesnut-colour with a ring of the brightest emerald-green. Its wings are in proportion strong, and the quill-feathers dark, with red shining plumes, spots, and stripes. The tail is straight, short, and brown. Two long naked black shafts project from the rump, at least a hand-breadth beyond the tail, having at their extremities semilunar twisted plumage, of the most glaring green colour above, and dusky below. The belly is white and green sprinkled; and on each side is a tuft of long plumage, feathered with a broad margin, being on one side green and on the other dusky. The back is blood-red and brown, shining like silk. The legs are in size like those of a lark, three fore-toes and one back-toe. This bird associates not with any of the other birds of Paradise; but flits solitary from bush to bush, wherever he sees red berries, without ever getting on tall trees.

PARADOX, in philosophy, a proposition seemingly absurd, as being contrary to some received opinion, but yet true in fact.

No science abounds more with paradoxes than geometry: thus, that a right line should continually approach to the hyperbola, and yet never reach it, is a true paradox; and in the same manner, a spiral may continually approach to a point, and yet not reach it, in any number of revolutions, however great.

PARALLACTIC, in general, something relating to the parallax of heavenly bodies. See PARALLAX.

The parallactic angle of a star, &c. is the difference of the angles CEA (Plate Miscell. fig. 179.), BTA, under which its true and apparent distance from the zenith is seen; or, which is the same thing, it is the angle TSE.

The sines of the parallactic angles ALT, AST (fig. 180.), at the same or equal distances, ZS, from the zenith, are in the reciprocal ratio of the distances TL and TS from the centre of the earth.

PARALLAX, in astronomy, denotes a change of the apparent place of any heavenly body, caused by being seen from different points of view; or it is the difference between the true and apparent distance of any heavenly body from the zenith.

Thus let AB (Plate Miscel. fig. 181.) be a quadrant of a great circle on the earth's surface, A the place of the spectator, and the point V in the heavens the vertex and zenith. Let VNH represent the starry firmament, AD the sensible horizon, in which suppose the star C to be seen, whose distance from the centre of the earth is TC. If this star was observed from the centre T, it would appear in the firmament in E, and elevated above the horizon by the arch DE: this point E is called the true place of the phænomenon or star. But an observer viewing it from the surface of the earth at A, will see it at D, which is called its visible or apparent place; and the arch DE, the distance between the true and visible place, is what astronomers call the parallax of the star, or other phænomena.

If the star rises higher above the horizon to M, its true place visible from the centre is P, and its apparent place N; whence its parallax will be the arch PN, which is less than the arch DE. The horizontal parallax, therefore, is the greatest; and the higher a star rises, the less is its parallax; and if it should come to the vertex or zenith, it would have no parallax at all: for when it is in Q, it is seen both from T and A in the same line TAV, and there is no difference between its true and apparent or visible place. Again, the farther a star is distant from the earth, so much the less is its parallax: thus the parallax of the star F is only GD, which is less than DE the parallax of C. Hence it is plain that the parallax is the difference of the distances of a star from the zenith when seen from the centre and from the surface of the earth: for the true distance of the star M from the zenith is the arch VP, and its apparent distance VN, the difference between which PN is the parallax.

These distances are measured by the angles VTM and VAM, but VAM — VTM = TMA. For the external angle VAM = ∠ ATM + ∠ AMT, the two inward and opposite angles; so that AMT measures the parallax, and upon that account is itself frequently called the parallax: and this is always the angle under which the semidiameter of the earth, AT, appears to an eye placed in the star; and therefore where this semidiameter is seen directly, there the parallax is greatest, viz. in the horizon. When the star rises higher, the sine of the parallax is always to the sine of the star's distance from the zenith, as the semidiameter of the earth to the distance of the star from the earth's centre: hence if the parallax of a star is known at any one distance from the zenith, we can find its parallax at any other distance.

If we have the distance of a star from the earth, we can easily find its parallax: for on the triangle TAC (fig. 181.) rectangular at A, having the semidiameter of the earth, and TC the distance of the star, the angle ACT, which is the horizontal parallax, is found by trigonometry; and, on the other hand, if we have this parallax, we can find the distance of the star; since in the same triangle, having AT, and the ∠ ACT, the distance TC may be easily found.

Astronomers, therefore, have invented several methods for finding the parallaxes of stars, in order thereby to discover their distances from the earth. However, the fixed stars are so remote as to have no sensible parallax; and even the sun, and all the primary planets, except Mars and Venus when in perigee, are at so great distances from the earth, that their parallax is too small to be observed. In the moon, indeed, the parallax is found to be very considerable, which in the horizon amounts to a degree or more, and may be found thus: In an eclipse of the moon, observe when both its horns are in the same vertical circle, and at that instant take the altitudes of both horns: the difference of these two altitudes being halved and added to the least, or subtracted from the greatest, gives nearly the visible or apparent altitude of the moon's centre; and the true altitude is nearly equal to the altitude of the centre of the shadow at that time. Now we know the altitude of the shadow, because we know the place of the sun in the ecliptic, and its depression under the horizon, which is equal to the altitude of the opposite point of the ecliptic in which is the centre of the shadow. And therefore having both the true altitude of the moon and the apparent altitude, the difference of these is the parallax required. But as the parallax of the moon increases as she approaches towards the earth, or the perigæum of her orbit, therefore astronomers have made tables, which shew the horizontal parallax for every degree of its anomaly.

The parallax always diminishes the altitude of a phænomenon, or makes it appear lower than it would do if viewed from the centre of the earth; and this change of the altitude may, according to the different situation of the ecliptic and equator in respect of the horizon of the spectator, cause a change of the latitude, longitude, declination, and right ascension of any phænomenon, which is called their parallax. The parallax, therefore, increases the right and oblique ascension; diminishes the descension; diminishes the northern declination and latitude in the eastern part, and increases them in the western; but increases the southern both in the eastern and western part; diminishes the longitude in the western part, and increases it in the eastern. Hence it appears, that the parallax has just opposite effects to refraction.

Parallax, *annual*, the change of the apparent place of a heavenly body, which is caused by being viewed from the earth in different parts of its orbit round the sun. The annual parallax of all the planets is found very considerable, but that of the fixed stars is imperceptible.

PARALLEL, in geometry, an appellation given to lines, surfaces, and bodies, every where equidistant from each other; and which, though infinitely produced, would never meet.

Parallel planes, are such planes as have all the perpendiculars drawn betwixt them equal to each other.

Parallel rays, in optics, are those which keep at an equal distance from the visible object to the eye, which is supposed to be infinitely remote from the object.

Parallel ruler, an instrument consisting of two wooden, brass, &c. rulers, equally broad every where; and so joined together by cross blades as to open to different intervals, accede and recede, and yet still retain their parallelism. See Instruments, *mathematical*.

The use of this instrument is obvious; for one of the rulers being applied to a given line, and the other withdrawn to a given point, a right line drawn by its edge through that point, is a parallel to the given line.

Parallels, or Parallel circles, in geography, called also parallels or circles of latitude, are lesser circles of the sphere conceived to be drawn from west to east, through all the points of the meridian, commencing from the equator to which they are parallel, and terminating with the poles. They are called parallels of latitude, because all places lying under the same parallel, have the same latitude.

Parallels *of latitude*, in astronomy, are lesser circles of the sphere parallel to the ecliptic, imagined to pass through every degree and minute of the colures. They are represented on the globe by the divisions on the quadrant of altitude, in its motion round the globe, when screwed over the pole of the ecliptic. See Globe.

Parallels *of altitude*, or Almucantars, are circles parallel to the horizon, imagined to pass through every degree and minute of the meridian between the horizon and zenith, having their poles in the zenith. They are represented on the globe by the divisions on the quadrant of altitude, in its motion about the body of the globe, when screwed to the zenith.

Parallels *of declination*, in astronomy, are the same with parallels of latitude in geography.

Parallel sphere, that situation of the sphere, wherein the equator coincides with the horizon, and the poles with the zenith and nadir. In this sphere all the parallels of the equator become parallels of the horizon, consequently no stars ever rise or set, but all turn round in circles parallel to the horizon; and the sun, when in the equinoctial, wheels round the horizon the whole day. After his rising to the elevated pole, he never sets for six months; and after his entering again on the other side of the line, never rises for six months longer.

This is the position of the sphere to such as live under the poles, and to whom the sun is never higher than 23° 30′.

Parallel sailing, in navigation, is the sailing under a parallel of latitude. See Navigation.

PARALLELEPIPED, or Parallelopiped, in geometry, a regular solid comprehended under six parallelograms, the opposite ones whereof are similar, parallel, and equal. See Geometry.

All parallelepipeds, prisms, cylinders, &c. whose bases and heights are equal, are themselves equal.

A diagonal plane divides a parallelepiped into two equal prisms; so that a triangular prism is half a parallelepiped upon the same base and of the same altitude.

All parallelepipeds, prisms, cylinders, &c. are in a ratio compounded of their bases and altitudes: wherefore, if their bases are equal, they are in proportion to their altitudes; and conversely.

All parallelepipeds, cylinders, cones, &c. are in a triplicate ratio of their homologous sides, and also of their altitudes.

Equal parallelepipeds, prisms, cones, cylinders, &c. reciprocate their bases and altitudes.

PARALLELISM *of the earth's axis.* See ASTRONOMY.

PARALLELOGRAM. See GEOMETRY.

PARALOGISM, in logic, a false reasoning, or a fault committed in demonstration, when a consequence is drawn from principles that are false; or, though true, are not proved; or when a proposition is passed over that should have been proved by the way.

PARALYSIS, *the palsy.* See MEDICINE.

PARAMECIUM, a genus of the order vermes infusoria, invisible to the naked eye, simple, pellucid, flattened, oblong. There are seven species. The P. aurelia is compressed, longitudinally plaited towards the fore-part, acute behind. It is found in ditch-water and infusions; membranaceous, four times as long as it is broad, the fore-part obtuse, hyaline; the hind part filled with molecules; the gold reaching from the middle to the tip.

PARAMETER, in conic sections, a constant line, otherwise called latus rectum. See CONIC SECTIONS.

The parameter is said to be constant, because in the parabola the rectangle under it and any abscis is always equal to the square of the corresponding semiordinate; and in the ellipsis and hyperbola, it is a third proportional to the conjugate and transverse axis.

Thus, if t and c are the two axes in the ellipse and hyperbola, and x and y an abscis and its ordinate in the parabola: it will be

$t : c :: c : p = \frac{c^2}{t}$ the parameter in the ellipse and hyperbola,

and $x : y :: y : p = \frac{y^2}{x}$ the parameter in the parabola.

PARAMOUNT, the supreme or highest lord of the fee. This seigniory of a lord paramount is frequently termed an honour, and not a manor; especially if it has belonged to an antient feudal baron, or has been at any time in the hands of the crown. 2 Black. 91.

PARAPET, in fortification, an elevation of earth designed for covering the soldiers from the enemy's cannon or small shot. The thickness of the parapet is from 18 to 20 feet; its height is six feet on the inside, and four or five on the outside. It is raised on the rampart, and has a slope above called the superior talus, and sometimes the glacis of the parapet. The exterior talus of the parapet is the slope facing the country: there is a banquette or two for the soldiers who defend the parapet to mount upon, that they may the better discover the country, fosse, and counterscarp, and fire as they find occasion.

Parapet of the covert way, or corridor, is what covers that way from the sight of the enemy, which renders it the most dangerous place for the besiegers, because of the neighbourhood of the faces, flanks, and curtains of the place.

PARAPET, is also a little wall raised breast-high on the banks of bridges, quays, or high buildings, to serve as a stay, and prevent people falling over.

PARAPHERNALIA, are the woman's apparel, jewels, and other things, which, in the life-time of her husband, she wore as the ornaments of her person, to be allowed by the discretion of the court, according to the quality of her and her husband. The husband cannot devise such ornaments and jewels of his wife; though, during his life, he has power to dispose of them. But if she continues in the use of them till his death, she shall afterwards retain them against his executors and administrators, legatees, and all other persons, except creditors where there is a deficiency of assets. 2 Black. 436.

PARAPLEGIA, or PARAPLEXIA, in medicine, a species of paralysis or palsy, usually succeeding an apoplexy. See MEDICINE.

PARASANG, an antient Persian measure, different at different times, and in different places; being sometimes 30, sometimes 40, and sometimes 50 stadia or furlongs.

PARASITES, or PARASITICAL PLANTS, in botany, such plants as are produced out of the trunk or branches of other plants, from whence they receive their nourishment, and will not grow upon the ground, as the misleto, &c.

PARCEL-MAKERS, two officers in the exchequer, who make parcels of the escheator's accounts, in which they charge them with every thing they have levied for the king's use, within the time of their office, and deliver the same to one of the auditors of the court, to make their accounts therewith.

PARCHMENT, in commerce, the skin of sheep or goats prepared after such a manner as to render it proper for writing upon, covering books, &c.

The manufacture of parchment is begun by the skinner, and finished by the parchment-maker. The skin having been stripped of its wool, and placed in the lime-pit, in the manner described under the article SHAMMY, the skinner stretches it on a kind of frame, and pares off the flesh with an iron instrument; this done, it is moistened with a rag, and powdered chalk being spread over it, the skinner takes a large pumice-stone, flat at bottom, and rubs over the skin, and thus scours off the flesh; he then goes over it again with the iron instrument, moistens it as before, and rubs it again with the pumice-stone without any chalk underneath: this smooths and softens the flesh-side very considerably. He then drains it again, by passing over it the iron instrument as before. The flesh-side being thus drained, by scraping off the moisture, he in the same manner passes the iron over the wool or hair side: then stretches it tight on a frame, and scrapes the flesh-side again: this finishes its draining; and the more it is drained, the whiter it becomes. The skinner now throws on more chalk, sweeping it over with a piece of lamb-skin that has the wool on, and this smooths it still farther. It is now left to dry, and when dried, taken off the frame by cutting it all round. The skin thus far prepared by the skinner, is taken out of his hands by the parchment-maker, who first, when it is dry, pares it on a summer (which is a calf-skin stretched in a frame) with a sharper instrument than that used by the skinner, and working with the arm from the top to the bottom of the skin, takes away about one-half of its thickness. The skin thus equally pared on the flesh-side, is again rendered smooth, by being rubbed with the pumice-stone, on a bench covered with a sack stuffed with flocks, which leaves the parchment in a condition fit for writing upon. The parings thus taken off the leather, are used in making glue, size, &c.

What is called vellum, is only parchment made of the skins of abortives, or at least sucking calves. This has a much finer grain, and is whiter and smoother than parchment; but is prepared in the same manner, except in not being passed through the lime-pit.

PARDON, is the remitting or forgiving a felony or other offence committed against the king.

Blackstone mentions the power of pardoning offences to be one of the greatest advantages of monarchy in general above every other form of government; and which cannot subsist in democracies. Its utility and necessity are defended by him on all those principles which do honour to human nature. See 4 Black. 396.

Pardons are either general or special; general as by act of parliament, of which, if they are without exceptions, the court must take notice ex officio; but if there are exceptions therein, the party must aver that he is none of the persons excepted. 3 Inst. 233.

Special pardons are either of course, as to persons convicted of manslaughter, or se defendendo, and by several statutes to those who shall discover their accomplices in several felonies; or of grace, which are by the king's charter, of which the court cannot take notice ex officio, but they must be pleaded. 3 Inst. 233.

A pardon may be conditional, that is, the king may extend his mercy upon what terms he pleases; and may annex to his bounty a condition either precedent or subsequent, on the performance whereof, the validity of the pardon will depend; and this by the common law. 2 Haw. 37.

All pardons must be under the great seal. The effect of a pardon is to make the offender a new man; to acquit him of all corporal penalties and forfeitures annexed to that offence; and to give him a new credit and capacity: but nothing but an act of parliament can restore or purify the blood after an attainder.

PAREGORICS. See PHARMACY.

PARENCHYMA *of plants*, that part of the plant that lies immediately below the epidermis. It is of a deep-green colour, very tender, and succulent. See PLANTS, *physiology of.*

PARENTHESIS, in grammar, certain intercalary words, inserted in a discourse, which interrupt the sense or thread, but seem necessary for the better understanding of the subject.

PARENTS AND CHILDREN. If parents run away, and leave their children at the charge of the parish, the churchwardens and overseers, by order of the justices, may seize the rents, goods, and chattels, of such parents, and dispose thereof towards their children's maintenance.

A parent may lawfully correct his child, being under age, in a reasonable manner; but the legal power of the father over the persons of his children, ceases at the age of 21. 1 Black. 452.

PARHELION. See OPTICS.

PARIAN CHRONICLE. See ARUNDELIAN MARBLES.

PARIAN MARBLE, in the natural history of the antients, the white marble used then, and to this day, for carving statues, &c. and called by us at this time statuary marble. Too many of the later writers have confounded all the white marbles under the name of the Parian; and among the workmen, this and all the other white marbles have the common name of alabasters; so that it is in general forgotten among them that there is such a thing as alabaster different from marble; which, however, is truly the case. Almost all the world also have confounded the Carrara marble with this, though they are really very different; the Carrara kind being of a finer structure and clearer white than the Parian, but less bright and splendid, harder to cut, and not capable of so glittering a polish. The true Parian marble has usually somewhat of a faint blueish tinge among the white, and often has blue veins in different parts of it.

PARIANA, a genus of the monœcia polyandria class and order. The male flowers in whorls, forming spikes; calyx two-valved; corolla two-valved, larger than the calyx; filaments 40. Female flowers solitary in each whorl; calyx two-valved; corolla two-valved; stigma two-seeded, three-cornered. There is one species, of no note.

PARIETALIA OSSA. See ANATOMY.

PARIETARIA, *pellitory of the wall*, a genus of the monœcia order, in the polygamia class of plants, and in the natural method ranking under the 53d order, scabridæ. The calyx of the hermaphrodite is quadrifid; there is no corolla; there are four stamina; one style; and one seed, superior and elongated. The female calyx is quadrifid; there is no corolla; nor are there any stamina. There is one style; and one seed, superior and elongated. There are 10 species, of which one, named the officinalis, is used in medicine. The plant has a cooling and diuretic quality. Three ounces of the juice taken internally, or a fomentation externally applied, have been found serviceable in the strangury. The plant laid upon heaps of corn infested with weevils, is said to drive away those destructive insects. See Plate Nat. Hist. fig. 316.

PARIS, *herb Paris*, or *truelove*, a genus of the trigynia order, in the octandria class of plants, and in the natural method ranking under the 11th order, sarmentaceæ. The calyx is tetraphyllous; there are four petals, narrow in proportion; the berry quadrilocular. There is but one species, growing naturally in woods and shady places in England. It has a single naked stem, greenish blossoms, and blueish-black berries. Though this plant has been reckoned of a poisonous nature, being ranked among the aconites, yet late authors attribute quite other properties to it, esteeming it to be a counter-poison, and good in malignant and pestilential fevers.

PARISH. In England there are 9913 parishes, of which 3845 are churches impropriate, and the rest are annexed to colleges or church dignities. In many of these parishes, on account of their large extent and the number of parishioners, there are several chapels of ease.

PARISH-OFFICERS, officers chosen annually to regulate and manage the concerns of the parish.

PARK, a piece of ground inclosed and stored with wild beasts of chase, which a man may have by prescription or the king's grant.

By 16 Geo. III. c. 30. if any person shall pull down or destroy the pale or wall of a park, he shall forfeit 30*l*.

PARK *of artillery*. See ARTILLERY, *park of*.

PARKINSONIA, so called in honour of the English botanist Parkinson, a genus of the monogynia order, in the decandria class of plants, and in the natural method it ranks under the 33d order, lomentaceæ. The calyx is quinquefid; there are five petals, all of them oval except the lowest, which is reniform; there is no style; the legumen moniliform, or like strung beads. We know but one species of this plant, which is very common in the Spanish West Indies, but has of late years been introduced into the English settlements, for the beauty and sweetness of its flowers. In the countries where it grows naturally, it rises to be a tree of 20 or more feet high, and bears long slender bunches of yellow flowers, which have a most agreeable sweet scent.

PARLIAMENT, is the legislative branch of the supreme power of Great Britain, consisting of the king, the lords spiritual and temporal, and the knights, citizens, burgesses, representatives of the commons of the realm, in parliament assembled.

The power and jurisdiction of parliament is so transcendant and absolute, that it cannot be confined, either for causes or persons, within any bounds. 4 Inst. 36.

The house of commons is a denomination given to the lower house of parliament. In a free state, every man, who is supposed a free agent, ought to be, in some measure, his own governor; and therefore a branch at least of the legislative power should reside in the whole body of the people. In elections for representatives for Great Britain, antiently, all the people had votes; but king Henry VI. to avoid tumults, first appointed that none should vote for knights but such as were freeholders, did reside in the county, and had forty shillings yearly revenue. In so large a state as ours, therefore, it is very wisely contrived, that the people should do that by their representatives which it is impracticable to perform in person; representatives chosen by a number of minute and separate districts, wherein all the voters are or may be easily distinguished. The counties are therefore represented by knights, elected by the proprietors of lands; the cities and boroughs are represented by citizens and burgesses, chosen by the mercantile or supposed trading interest of the nation.

The peculiar laws and customs of the house of commons, relate principally to the raising of taxes, and the elections of members to serve in parliament.

The method of making laws is nearly the same in both houses. In the house of commons, in order to bring in the bill, if the relief sought is of a private nature, it is first necessary to prefer a petition; which must be presented by a member, and usually set forth a grievance required to be remedied. This petition, when founded on facts of a disputable nature, is referred to a committee of members, who examine the matter alleged, and accordingly report it to the house; and then (or otherwise upon the mere petition), leave is given to bring in the bill. In public matters, the bill is brought in upon motion made to the house, without any petition.

If the bill begins in the house of lords, if of a private nature, it is referred to two judges, to make report. After the second reading, the bill is said to be committed, that is, referred to a committee; which is selected by the house, in matters of small importance; or upon a bill of consequence, the house resolves itself into a committee of the whole house. A committee of the whole house is composed of every member; and to form it the speaker quits the chair, and may consequently sit and debate upon the merits of it as a private member, another member being appointed chairman for the time. In these committees the bill is usually debated clause by clause, amendments made, and sometimes it is entirely new-modelled. Upon the third reading, further amendments are sometimes made; and if a new clause is added, it is done by tacking a separate piece of parchment on the bill, which is called a rider. 1 Black. 182.

The royal assent may be given two ways: 1. in person, when the king comes to the house of peers, in his crown and royal robes, and sending for the commons to the bar, the titles of all the bills that have passed both houses are read; and the king's answer is declared by the clerk of the parliament. If the king consents to a public bill, the clerk usually declares, *le roy le veut*, the king wills it so to be; if to a private bill, *soit fait comme il est desiré*, be it as it is desired. If the king refuses his assent, it is in the gentle language of, *le roy s'avisera*, the king will advise upon it. When a bill of supply is passed, it is carried up and presented to the king by the speaker of the house of commons; and the royal assent is thus expressed, *le roy remercie ses loyal sujets, accepte leur benevolence, et aussi le veut;* the king thanks his loyal subjects, accepts their benevolence, and also wills it so to be. By the stat. 33 Hen. VIII. c. 21., the king may give his assent by letters patent under his great seal, signed with his hand, and notified in his absence to both houses assembled together in the upper house. And when the bill has received the royal assent in either of these ways, it is then, and not before, a statute or act of parliament.

An act of parliament thus made is the exercise of the highest authority that this kingdom acknowledges upon the earth. It has power to bind every subject in the land, and the dominions thereunto belonging, nay even the king himself, if particularly named in it; and it cannot be altered, amended, dispensed with, suspended, or repealed, but in the same forms, and by the same authority, of parliament.

Adjournment is no more than a continuance of the session from one day to another, as the word itself signifies; and this is done by the authority of each house separately every day, or for a longer period; but the adjournment of one house is no adjournment of the other. 1 Black. 186.

Prorogation is the continuance of the parliament from one session to another, as an adjournment is a continuation of the session from day to day. And this is done by the royal authority, expressed either by the lord chancellor in his majesty's presence, or by commission from the crown, or frequently by proclamation; and by this, both houses are prorogued at the same time, it not being a prorogation of the house of lords or commons, but of the parliament. The session is never understood to be at an end until a prorogation; though unless some act is passed, or some judgment given in parliament, it is in truth no session at all. Id.

A dissolution is the civil death of the parliament; and this may be effected three ways: 1. By the king's will expressed either in person or representation; 2. By the demise of the crown; 3. By the length of time.

By the king's will; for as the king has the sole right of convening the parliament, so also it is a branch of the royal prerogative, that he may, whenever he pleases, prorogue the parliament for a time, or put a final period to its existence.

By the demise of the crown: this dissolution formerly happened immediately upon the death of the reigning sovereign; but the calling a new parliament immediately on the inauguration of the successor being found inconvenient, and dangers being apprehended from having no parliament in being, in case of a disputed succession, it was enacted by statutes 7 and 8 W. III. c. 15., and 6 Anne, c. 7., that the parliament in being shall continue for six months after the death of any king or queen, unless sooner prorogued or dissolved by the successor; that if the parliament is at the time of the king's death separated by adjournment or prorogation, it shall notwithstanding assemble immediately; and that if no parliament is then in being, the members of the last parliament shall assemble and be again a parliament.

Lastly, a parliament may be dissolved or expire by length of time.

The utmost extent of time that the same parliament was allowed to sit by the stat. of 6 W. c. 3. was three years; after the expiration of which, reckoning from the return of the first summons, the parliament was to have no longer continuance. But by stat. 1. Geo. I. c. 38. in order professedly to prevent the great and continued expences of frequent elections, and the violent heats and animosities consequent thereupon, and for the peace and security of the government just then recovering from the late rebellion, this term was prolonged to seven years. So that as our constitution now stands, the parliament must expire, or die a natural death, at the end of every seventh year, if not sooner dissolved by the royal prerogative. See ELECTION.

PARLIAMENT, *the high court of*, is the supreme court of the kingdom, not only for the making but also for the execution of laws, by the trial of great and enormous offenders, whether lords or commoners, in the method of parliamentary impeachment. An impeachment before the lords, by the commons of Great Britain in parliament, is a prosecution of the already known and established law, and has been frequently put in practice; being a presentment to the most high and supreme court of criminal jurisdiction by the most solemn grand inquest of the whole kingdom. A commoner cannot, however, be impeached before the lords for any capital offence, but only for high misdemeanors; a peer may be impeached for any crime. And they usually, in case of an impeachment of a peer for treason, address the crown to appoint a lord high steward, for the greater dignity and regularity of their proceedings; which high steward was formerly elected by the peers themselves, though he was generally commissioned by the king; but it has of late years been strenuously maintained, that the appointment of a high steward in such cases is not indispensably necessary, but the house may proceed without one. The articles of impeachment are a kind of bills of indictment, found by the house of commons, and afterwards tried by the lords; who are in cases of misdemeanors considered not only as their own peers, but as the peers of the whole nation.

PARNASSIA, *grass of Parnassia*, a genus of the tetragynia order, in the pentandria class of plants. The calyx is quinquepartite; there are five petals, and as many nectaria, heart-shaped, and ciliated with globular tops; the capsule quadrivalved. There is but one species, having a stalk about a foot high, angular, and often a little twisted, bearing a single white flower at top. The flowers are very beautifully streaked with yellow; so that though it is a common plant, growing naturally in moist pastures, it is frequently admitted into gardens.

PAROLE, a term signifying any thing done verbally or by word of mouth, in contradistinction to what is written; thus an agreement may be by parole. Evidence also may be divided into parole evidence and written evidence. A parole release is good to discharge a debt by simple contract. 2 Show. 417. The holder of a bill of exchange may authorize another to indorse his name upon it.

PAROLE EVIDENCE. See EVIDENCE.

PARONYCHIA, *whitlow*. See SURGERY.

PAROTIDES. See ANATOMY.

PAROXYSM. See MEDICINE.

PARRA, a genus of birds belonging to the order of grallæ; the characters of which are: the bill is tapering and a little obtuse; the nostrils are oval, and situated in the middle of the bill; the forehead is covered with fleshy caruncles, which are lobated; the wings are small and spinous. There are five species; of which the most remarkable is the chavaria, which is about the size of a domestic cock. The Indians in the neighbourhood of Carthagena, who breed large flocks of poultry that stray in the woods, and train up the chavaria to defend them against the numerous birds of prey, no one of which will dare to encounter it. It is never known to desert the flock, and it returns every evening to roost.

The parra Dominica is about the size of the lapwing. The bill is yellow, as are also the head and upper parts; the under are of a yellowish-white bordering on rose-colour: the legs are also yellow. This species inhabits several of the warmer parts of America and St. Domingo.

The parra Senegalla, is about the same size with the former. Its bill is also yellow, tipped with black; the forehead is covered with a yellow skin, the chin and throat are black, the head and upper parts of the body and lesser wing-coverts are grey-brown. The lower part of the belly, and the upper and under tail-coverts, are dirty white. At the bend of the wing is a black spur. It inhabits Senegal, and thence derives its name.

The parra jacana, or spur-winged water-hen, is about the size of the water-rail. The bill is in length about an inch and a quarter, of an orange-colour; and on the forehead is a membranous flap, half an inch long, and nearly as broad. On each side of the head also is another of the same, about a quarter of an inch broad; and both together they surround the base of the bill. The head, throat, neck, breast, and under-parts, are black; and sometimes the belly is mixed with white, &c. The birds of this species inhabit Brasil, Guiana, and Surinam; but are equally common at St. Domingo, where they frequent the marshy places, sides of ponds, and streams, and wade quite up to the thighs in the water. They are also generally seen in pairs, and when separated call each other continually till they join again. They are very shy, and most common in the rainy seasons in May and November. They are at all times very noisy; their cry sharp and shrill, and may be heard a great way off. This, as well as the other species, is called by the French chirurgien. The flesh is accounted pretty good.

The parra variabilis, or spur-winged water-hen, is about nine inches long. The bill is about 14 inches in length, and in colour is orange-yellow. On the forehead is a flap of red skin; the crown of the head is brown, marked with spots of a darker colour; the hind part of the neck is much the same, but of a deeper dye. On the forepart of the wing is a yellow spur, &c. The legs are furnished with long toes, as in all the others, the colour of which is blueish ash. This species inhabits Brasil, and is said to be pretty common about Carthagena, and in South America. There are five species in all.

PARRELS, in a ship, are frames made of trucks, ribs, and ropes, which having both their ends fastened to the yards, are so contrived as to go round about the masts, that the yards, by their means, may go up and down upon the masts: these also, with the breast-ropes, fasten the yards to the masts.

PARROT, and PARROQUET. See PSITTACUS.

PARSLEY. See APIUM.

PARSNEP. See PASTINACA.

PARSON, signifies the incumbent of a church. He is in himself a body corporate, in order to protect and defend the rights of the church by a perpetual succession. When a parson is instituted and inducted into a rectory, he is then, and not before, in full and complete possession. 1 Black. 391.

PART, in music, the name of each of the melodies of any harmonic composition, and which, when performed in union, form its harmony. Four is the fewest number of parts with which the chords necessary to elaborate harmony can be completely filled.

PARTERRE, in gardening, a level division of ground, which, for the most part, faces the south, and best front of a house; and is generally furnished with greens, flowers, &c.

PARTHENIUM, a genus of the pentandria order, in the monœcia class of plants, and in the natural method ranking under the 49th order, compositæ. The male calyx is common and pentaphyllous; the florets of the disk monopetalous. The female has five florets of the radius, each with two male florets behind it; the intermediate female superior; the seed is naked. There are two species.

This plant has been much neglected in Europe, having, on account of its smell, been banished from our parterres. It is therefore indebted for its culture to the distinguished rank it holds among the Chinese flowers. The skill of their florists, and their continual care, have brought it to so great perfection, that Europeans scarcely know it. They have, by their attention to its culture, procured more than 300 varieties of it, and every year produces a new one.

PARTI, Partie, Party, or Parted, in heraldry, is applied to a shield or escutcheon, denoting it divided or marked out into partitions. See Heraldry.

PARTICIPLE, in grammar, an adjective formed of a verb, so called because it participates partly of the properties of a noun, and partly of those of a verb.

PARTICLE, in grammar, a denomination for all those small words that tie or unite others together, or that express the modes or manners of words.

PARTIES, in law, signify the persons that are named in a deed or fine, viz. those that made the deed, or levied the fine, and also those to whom the same was made or levied. Here it is to be observed, that if an indenture was made between two parties, mentioned particularly in the beginning of the deed, and therein one of them grants to another that is not named at the beginning thereof, such person is no party to that deed, nor can take any thing thereby. The parties to a suit at law are the plaintiff and defendant, who carry on the suit.

PARTITION, in law, signifies a division of lands, &c. descended by common law or custom among coheirs or parceners, being two at least. Partition may also be made by joint tenants, and tenants in common, by assent, deed, or writ.

PARTNER If there are several joint partners, and a person has dealings generally with one of them in matters concerning their joint trade, whereby a debt becomes due to the said person, it shall charge them jointly and the survivors of them; but if the person only dealt with one of the partners upon a separate account, in that case the debt shall only affect that partner and his executors. If one or more of the joint traders become bankrupt, his or their proportions are only assignable by the commissioners, to be held in common with the rest who are not bankrupts. If one of two partners becomes a bankrupt, the commissioners cannot meddle with the interest of the other, for it is not affected with the bankruptcy of his companion. Payment to one of the partners, is payment to them all.

PARTRIDGE, in ornithology See Tetrao.

PARUS, or Titmouse, in ornithology, a genus belonging to the order of passeres. The bill is very entire, covered at the basis with hairs; the tongue is truncated and hairy. There are 14 species, of which the most remarkable are:

1. The cristatus, or crested titmouse, weighs 13 pennyweights; the bill is black, with a spot of the same colour above it; all the upper part of the body grey; the neck and under parts are white, with a faint tincture of red, which is deepest just below the wings. The legs are of a lead-colour. It erects its crown feathers into a crest. It inhabits the warm parts of North America, and frequents forest-trees, feeding upon insects.

2. The major, or great titmouse, has the head and throat black, the cheeks white, the back of a green colour, the belly yellowish-green, divided in the middle by a bed of black, which extends to the vent; the rump of a bluish-grey, the legs of a lead-colour, the toes divided to the very origin, and the back toe very large and strong. This species sometimes visits our gardens; but for the most part inhabits woods, where it builds in hollow trees, laying about ten eggs. It feeds on insects, which it finds in the bark of trees. In the spring they do a great deal of mischief by picking off the tender buds of the fruit trees. Like woodpeckers, they are perpetually running up and down the bodies of trees in quest of food. This bird has three cheerful notes, which it begins to utter in the month of February.

3. The caudatus, or long-tailed titmouse, is about five inches and a quarter in length, and seven inches in breadth. The bill is black, very thick and convex, differing from all others of this genus. The top of the head, from the bill to the hind part, is white, mixed with a few dark-grey feathers: this bed of white is entirely surrounded with a broad stroke of black, which, rising on each side of the upper mandible, passes over each eye, unites at the hind part of the head, and continues along the middle of the back to the rump. The feathers on each side of this black stroke are of a purplish red, as are those immediately incumbent on the tail. The tail is the longest in proportion to the bulk of any British bird, being in length three inches, the form not unlike that of a magpie, consisting of 12 feathers of unequal lengths, the middlemost the longest, those on each side growing gradually shorter. These birds are often seen passing through our gardens, going from one tree to another, as if in their road to some other place, never making any halt. They make their nests with great elegance, of an oval shape, and about eight inches deep, having near the upper end a hole for admission. The external materials are mosses and lichens curiously interwoven with wool. On the inside it is very warmly lined with a thick bed of feathers. The female lays from 10 to 17 eggs. The young follow their parents the whole winter, and from the slimness of their bodies and great length of tail, appear while flying like as many darts cutting the air.

4. The remiz, or small species of titmouse. It is called parus pendulinus, and is often found in Lithuania. Mr. Coxe, in his Travels through Poland, gives the following account of this little animal. "The wondrous structure of its pendant nest induced me to give an engraving of both that and the birds themselves. They are of the smallest species of titmice. The head is of a very pale bluish ash-colour; the forepart of the neck and the breast tinged with red; the belly white; wings black, back and rump of a yellowish rust-colour; quill feathers cinereous, with the exterior sides white; the tail rust-coloured. The male is singularly distinguished from the female by a pair of black-pointed whiskers. Its nest is in the shape of a long purse, which it forms with amazing art, by interweaving down, gossamer, and minute fibres, in a close and compact manner, and then lining the inside with down alone, so as to make a snug and warm lodge for its young brood. The entrance is at the side, small, and round, with its edge more strongly marked than the rest of this curious fabric: the bird, attentive to the preservation of its eggs or little ones from noxious animals, suspends it at the lesser end to the extremity of the slender twigs of a willow or some other tree over a river. Contrary to the custom of titmice, it lays only four or five eggs: possibly Providence hath ordained this scantiness of eggs to the remiz, because, by the singular instinct imparted to it, it is enabled to secure its young much more effectually from destruction than the other species, which are very prolific."

5. Macrocephalus, inhabits New Zealand. See Plate Nat. Hist. fig. 314.

PASPALUM, a genus of the triandria digynia class and order. The calyx is two-valved, orbicular; corolla of the same size; stigma pencilled. There are 15 species, all foreign grasses.

PASQUIN, a mutilated statue at Rome, in a corner of the palace of the Ursini: it takes its name from a cobler of that city called Pasquin, famous for his sneers and gibes, and who diverted himself with passing his jokes on all the people who went through that street. After his death, as they were digging up the pavement before his shop, they found in the earth the statue of an antient gladiator, well cut, but maimed, and half-spoiled: this they set up in the place where it was found, and by common consent named it Pasquin. Since that time all satires are attributed to that figure, and are either put into its mouth or pasted upon it, as if they were written by Pasquin redivivus; and these are addressed by Pasquin to Marforio, another statue at Rome. When Marforio is attacked, Pasquin comes to his assistance, and when Pasquin is attacked, Marforio assists him in his turn.

PASS, a straight, difficult, and narrow passage, which shuts up the entrance into a country. The first care of the general of an army is to seize the passes of the country into which he would carry the war, to fortify them, and take care that they are well guarded.

PASSAGE, or Passo, any phrase or short portion of any air, or other composition. Every member of a strain or movement is a passage.

Passage, *birds of*. See Migration.

PASSAGIO (Italian), a succession of sounds so connected in their melody and expression, as to form a member or phrase in the composition.

PASSANT. See Heraldry.

PASSERINA, in botany, a genus of the octandria monogynia class of plants, the flower of which is composed of a single petal, divided into four oval segments at the limb; the fruit is a coriaceous capsule, of an oval shape, with only one cell, and containing a single oval seed. There are 19 species.

PASSIFLORA, or Passion-flower, a genus of the pentandria order, in the gynandria class of plants, and in the natural method ranking under the 34th order, cucurbitaceæ. The calyx is pentaphyllous; there are five petals; the nectarium a crown; the berry is pedicellated. There are 36 diferent species, all of them natives of warm foreign countries, only one of which is sufficiently hardy to succeed well in the open ground here; all the others requiring the shelter of a greenhouse or stove, but chiefly the latter. The most remarkable are:

1. The cærulea, or blue-rayed common palmated passion-flower, with large spreading flowers, with whitish-green petals, and a blue radiated nectarium; succeeded by a large, oval, yellowish fruit. It is in flower from July until October; but the flowers are only of one day's duration, generally opening about 11 or 12 o'clock, and frequently in hot sunny weather burst open with elasticity, and continue fully expanded all that day; and the next they gradually close, assuming a decayed appearance, and never open any more.

2. The incarnata, or flesh-coloured Italian passion-flower, has leaves composed of three sawed lobes, each leaf attended by a twining tendril; and at the axillas long slender pedunculi, terminated each by one whitish flower, having a greenish calyx, and a reddish or purple radiated nectarium, surrounding the column of the fructification; which succeed to a large, round, fleshy fruit, ripening to a beautiful orange-colour.

3. The vespertilio, or bat's-wing passion-flower, has large, bilobate, or two-lobed leaves, the base roundish and glandular, the lobes acute, widely divaricated like a bat's wing, and dotted underneath; and axillary flowers, having white petals and rays.

4. Passiflora alata, one of the finest ornaments of our stoves.

As all the species are natives of warm climates, in this country they are mostly of a tender quality, except the first sort, which succeeds very well in the full ground, in a warm situation; only their young branches are sometimes killed in very severe winters; but plenty of new ones generally rise again in spring following; the others, denominated stove kinds, must always be retained in that repository.

PASSIONS, in painting: the passions are properly considered as subjects of painting, because being capable of representation by lines and colours, they fall within the province of that art, whose office it is to delineate all objects which can be expressed by those means. To represent the passions justly and fully, is however the utmost reach of the imitative art. The nicest accuracy is requisite, and the smallest deviation is frequently destructive of the whole effect intended to be produced.

Le Brun, a celebrated French painter, published a collection of heads, in which he gave examples of the appearances produced in the countenance by each distinct passion. But these examples are for the most part overcharged and gross. The student will find a much surer guide in the late publication of "The Anatomy of Painting," by Charles Bell, where the rules for delineating the passions are laid down with precision, by a fair demonstration of physical effects.

PASSPORT, or PASS, a licence or writing obtained from a prince or governor, granting liberty and safe conduct to pass through his territories without molestation. Passport also signifies a licence obtained for importing contraband goods, or for exporting and importing merchandise without paying the duties; these last licences are always given to ambassadors and other public ministers for their baggage, equipage, &c. If any person forges or counterfeits a passport, commonly called a Mediterranean pass, for any ship, or shall alter or erase any pass made out by the commissioners for executing the office of lord high admiral, or shall publish as true any forged, altered, or erased pass, knowing the same to be forged, &c. every such person being convicted in any part of his majesty's dominions where such offence may be committed, shall be guilty of felony without benefit of clergy, by 4 Geo. II. cap. 18. sect. 1.

PASTE, in the glass trade, a kind of coloured glass, made of calcined crystal, lead, and metallic preparations, so as to imitate the natural gems: for the manner of effecting which see GLASS.

PASTEBOARD. See PAPER.

PASTINACA, the *parsnip*, a genus of the digynia order, in the pentandria class of plants, and in the natural method ranking under the 45th order, umbellatæ. The fruit is an elliptical compressed plane; the petals are involuted and entire. There are only three species of this genus, the principal of which is the pastinaca sativa, or garden parsnip, which is an exceedingly fine esculent root. It is to be propagated by sowing the seeds in February or March, in a rich mellow soil, which must be deep dug, that the roots may be able to run deep without hindrance. It is a common practice to sow carrots at the same time upon the same ground with the parsnips; and if the carrots are designed to be drawn young there is no harm in it. The parsnips, when they are grown up a little, must be thinned to a foot distance, and carefully kept clear of weeds. They are finest tasted just at the season when the leaves are decayed; and such as are desirous to eat them in spring should have them taken up in autumn, and preserved in sand. They are useful for cattle.

PATEE, or PATTEE, in heraldry, a cross small in the centre, and widening to the extremes, which are very broad.

PATELLA. See ANATOMY.

PATELLA, or LIMPET, a genus of insects belonging to the order vermes testacea. The shells are of that class which is called univalves; they have no contour, and are in the form of little pointed cones. They are always attached to some hard body. Their summit is sometimes acute, sometimes obtuse, flatted, turned back, or perforated. The rock, or other hard body, to which they are always found adhering, serves as a kind of second or under shell to preserve them from injury; and for this reason Aldrovandus and Rondelet have classed them among the bivalves; but in this error they have not been followed by any other writer. The shells consist of carbonat of lime. But when exposed to a red-heat, they emit a smell like horn; and when dissolved in acids, a semi-liquid gelatinous matter was left behind. There are 36 species of this genus, which are principally distinguished by peculiarities in their shells. See Plate Nat. Hist. fig. 317.

PATENT, in general, denotes something that stands open or expanded: thus a leaf is said to be patent when it stands almost at right angles with the stalk.

PATENT, or *letters patent*, are writings sealed with the great seal of England, by which a man is authorized to do, or to enjoy, any thing, which of himself he could not do. They are called so by reason of their form; as being open, with their seal affixed, ready to be exhibited for the confirmation of the authority delegated by them.

PATHOLOGY, that part of medicine which explains the symptoms of diseases.

PATRON, in the canon and common law, is a person, who having the advowson of a parsonage, vicarage, or the like spiritual promotion, belonging to his manor, has, on that account, the gift and disposition of the benefice, and may present to it whenever it becomes vacant. The patron's right of disposing of a benefice originally arises either from the patron or his ancestors, &c. being the founders or builders of the church; from their having given lands for the maintenance thereof; or from the church's being built on their ground; and frequently from all three together. See ADVOWSON.

PAVEMENT. See PAVING.

PAVETTA, in botany, a genus of the tetrandria monogynia class of plants, with a monopetalous funnel-fashioned flower, and a monospermous berry. There are seven species, shrubs, natives of Africa, China, and the West Indies.

PAVILION. See ARCHITECTURE.

PAVILION, in heraldry, denotes a covering in form of a tent, which invests or wraps up the armories of divers kings and sovereigns, depending only on God and their sword.

PAVING, the construction of ground-floors, streets, or highways, in such a manner that they may be conveniently walked upon. In Britain the pavement of the grand streets, &c. is usually of flint or rubblestone; courts, stables, kitchens, halls, churches, &c. are paved with tiles, bricks, flags, or firestone; sometimes with a kind of freestone and ragstone. In some streets, as of Venice, the pavement is of brick: churches are sometimes paved with marble, and sometimes with mosaic work, as the church of St. Mark at Venice. In France the public roads, streets, courts, &c. are all paved with gres or grit, a kind of freestone. In Amsterdam, and the chief cities of Holland, they call their brick pavement the burgomasters' pavement, to distinguish it from the stone or flint pavement, which usually takes up the middle of the street, and which serves for carriages; the brick which borders it being destined for the passage of people on foot.

Pavements of freestone, flint, and flags, in streets, &c. are laid dry, that is, in a bed of sand; those of courts, stables, ground-rooms, &c. are laid in a mortar of lime and sand, or in lime and cement, especially if there are vaults or cellars underneath. Stonemasons, after laying a floor dry, especially of brick, spread a thin mortar over it; sweeping it backwards and forwards to fill up the joints. The several kinds of pavement are as various as the materials of which they are composed, and whence they derive the name by which they are distinguished: as,

1. Pebble-paving, which is done with

tones collected from the sea-beach, mostly brought from the islands of Guernsey and Jersey: they are very durable, indeed the most so of any stone used for this purpose. They are used of various sizes; but those which are from six to nine inches deep are esteemed the most serviceable. When they are about three inches deep they are denominated bolders or bowlers: these are used for paving court-yards, and other places not accustomed to receive carriages with heavy weights; and when laid in geometrical figures they have a very pleasing appearance.

2. Rag-paving was much used in London, but is very inferior to the pebbles; it is dug in the vicinity of Maidstone in Kent, from which it has the name of Kentish ragstone: there are squared stones of this material for paving coach-tracks and footways.

3. Purbeck pitchens, squared stones used in footways: they are brought from the island of Purbeck, and also frequently used in court-yards; they are in general from six to ten inches square, and about five inches deep.

4. Squared paving, for distinction by some called Scotch paving, because the first of the kind paved in the manner that has been and continues to be paved came from Scotland; the first was a clear close stone, called blue whynn, which is now disused because it has been found inferior to others since introduced in the order they are hereafter placed.

5. Granite, a hard material, brought also from Scotland, of a reddish colour, very superior to the blue whynn quarry, and at present very commonly used in London.

6. Guernsey, which is the best, and very much in use: it is the same stone with the pebble before spoken of, but broken with iron hammers, and squared to any dimensions required, of a prismoidal figure, set with its smallest base downwards. The whole of the foregoing paving should be bedded and paved in small gravel.

7. Purbeck paving, for footways, is in general got in large surfaces about two inches and a half thick; the blue sort is the hardest and the best of this kind of paving.

8. Yorkshire paving, is an exceeding good material for the same purpose; and is got of almost any dimensions of the same thickness as the Purbeck. This stone will not admit wet to pass through it, nor is it affected by the frost.

9. Ryegate, or firestone paving, is used for hearths, stoves, ovens, and such places as are liable to great heat, which does not affect the stone if kept dry.

10. Newcastle flags, are stones about two feet square, and one inch and a half or two inches thick: they answer very well for paving out-offices; they are somewhat like the Yorkshire.

11. Portland paving, with stone from the island of Portland: this is sometimes ornamented with black marble dots.

12. Swedland paving, is a black slate dug in Leicestershire, and looks well for paving halls, or in party-coloured paving.

13. Marble paving, is mostly variegated with different marbles, sometimes inlaid in mosaic.

14. Flat brick paving, done with brick laid in sand, mortar, or groute; as when liquid lime is poured into the joints.

15. Brick-on-edge paving, done with brick laid edgewise in the same manner. Bricks are also laid flat or edgewise in herring-bone. Bricks are also sometimes set endwise in sand, mortar, or groute. Paving is also performed with paving bricks; ten-inch tiles; foot tiles; clinkers for stables and outer-offices; and even with the bones of animals, for gardens, &c.

Pavements of churches, &c. frequently consist of stones of several colours; chiefly black and white, and of several forms, but chiefly squares and lozenges, artfully disposed. Indeed there needs no great variety of colours to make a surprising diversity of figures and arrangements. M. Truchet, in the Memoirs of the French Academy, has shewn by the rules of combination, that two square stones, divided diagonally into two colours, may be joined together chequerwise 64 different ways: which appears surprising enough, since two letters or figures can only be combined two ways.

The reason is, that letters only change their situation with regard to the first and second, the top and bottom remaining the same; but in the arrangement of these stones each admits of four several situations, in each whereof the other square may be changed 16 times, which gives 64 combinations.

Indeed, from a farther examination of these 64 combinations, he found there were only 32 different figures, each figure being repeated twice in the same situation, though in a different combination; so that the two differed from each other only by the transposition of the dark and light parts.

PAULICIANS, christians of the seventh century, disciples of one Constantine, a native of Armenia, and a favourer of the errors of Manes; who, as the name Manichees was become odious to all nations, gave those of his sect the title of Paulicians, on pretence that they followed only the doctrine of St. Paul.

PAULINIA, a genus of the trigynia order, in the octandria class of plants, and in the natural method ranking under the 23d order, trihilatæ. Its characters are these: the flower has a permanent empalement, composed of four small oval leaves; it has four oblong oval petals, twice the size of the empalement; and eight short stamina with a turbinated germen, having three short slender styles, crowned by spreading stigmas; the germen turns to a large three-cornered capsule with three cells, each containing one almost oval seed. There are 17 species, natives of the West Indies.

PAULIONISTS, in church history, christians of the third century, disciples of Paul Samosatensis, bishop of Antioch, who denied Christ's divinity, maintaining that when we call him the Son of God, we do not thereby mean that he is really and truly God; but only that he was so perfect a man, and so superior in virtue to all others, that he has this name given him by way of eminence.

PAVO, the *peacock*, in ornithology, a genus belonging to the order of gallinæ. The head is covered with feathers which bend backwards; the feathers of the tail are very long, and beautifully variegated with eyes of different colours. Latham enumerates eight species. The most remarkable are,

1. The cristatus, or common peacock, which is about the size of a common turkey; the length from the tip of the bill to the end of the tail being three feet eight inches. On the crown there is a sort of crest, composed of 24 feathers, which are not webbed except at the ends, which are gilded green. See Plate Nat. Hist. fig. 318. The female is rather less than the male.

This bird, now so common in Europe, is of Eastern origin, being a native of India. They are found wild in the islands of Ceylon and Java in the East Indies, and at St. Helena, at Barbuda, and other West India islands. They are not natural to China; but they are found in many places of Asia and Africa. They are, however, no where so large or so fine as in India, in the neighbourhood of the Ganges, whence, by degrees, they have spread into all parts, increasing in a wild state in the warmer climes, but wanting some care in the colder regions. In ours this bird does not come to its full plumage till the third year. The female lays five or six greyish white eggs; in hot climates 20, the size of those of a turkey. These, if let alone, she lays in some secret place, at a distance from her usual resort, to prevent their being broken by the male, which he is apt to do if he finds them. The time of sitting is from 27 to 30 days. The young may be fed with curd, chopped leeks, barley-meal, &c. moistened; and are fond of grasshoppers and some other insects. In five or six months they will feed as the old ones, on wheat and barley, with what else they can pick up in the circuit of their confinement. They are caught in India by carrying lights to the trees where they roost, and having painted representations of the bird presented to them at the same time; when they put out the neck to look at the figure, the sportsman slips a noose over the head, and secures his game. In most ages they have been esteemed as a salutary food. Hortensius gave the example at Rome, where it was carried to the highest luxury, and sold dear; and a young pea-fowl is thought a dainty even in the present times.

2. The pavo bicalcaratus is larger than the common pheasant. The feathers on the crown of the head are sufficiently long to form a crest, of a dull-brown colour. The neck is bright brown, striated across with dusky brown: the upper parts of the back, scapulars, and wing-coverts, are dull-brown, dotted with paler brown and yellowish; besides which each feather is marked near the end with a roundish large spot of a gilded purple colour, changing into blue and green in different lights; the lower part of the back and rump are dotted with white; all the under parts are brown, striated transversely with black. The female is a third smaller than the male. This species is of Chinese origin; and some of them have been brought from China to England alive.

3. The pavo tibetanus is about the size of a pintado, being about two feet and nearly two inches long. The head, neck, and under parts, are ash-coloured, marked with blackish lines: the wing-coverts, back, and rump, are grey, with small white dots; besides which, on the wing-coverts and back are large round spots of a fine blue, changing in different lights to violet and green gold. This species inhabits the kingdom of Thibet. The Chinese give it the name of chin-tchien-khi.

PAUPER, in law. See FORMA PAUPERIS.

PAUSE, in music, a mark or character, consisting of a curve drawn over a dot, and signifying that the note or the rest, over which it is placed, is to be continued beyond the regular time. The exact length of the pause is not dictated by any stated rule, but left to the judgment, taste, and feeling of the performer; who sometimes is licensed by the words ad libitum, to introduce extempore embellishments.

PAUSUS, a genus of insects, of the order coleoptera. The generic character is: antennæ of two joints, the upper very large, inflated, moveable, and hooked; head stretched forwards; wing-sheaths flexile, deflected, truncated.

1. Pausus microcephalus. The head is uncommonly small; the thorax broader than the head, and very uneven, the two parts being entirely separated by a transverse furrow. This rare insect is a native of Banana island, and Sierra Leone in Africa. Its colour is a blackish brown. It is represented on the Plate, both in its natural size, and considerably magnified.

The 2d species, or pausus sphærocerus, is thus described by Dr. Afzelius. "There was a house building for the governor, on an eminence at the south end of Free-town, in Sierra Leone. I had not resided there many days, when one evening, having just lighted my candle, and begun to write, I observed something dropping from the cieling before me upon the table, which, from its singular appearance, attracted my particular attention. It remained for a little while quite immoveable, as if stunned or frightened, but began soon to crawl very slowly and steadily. I then caught it, put it into a box, and left it confined there for a day or two. One evening, going to look at it, and happening to stand between the light and the box, so that my shadow fell upon the insect, I observed, to my great astonishment, the globes of the antennæ, like two lanthorns, spreading a dim phosphoric light. This singular phenomenon raised my curiosity, and, after having examined it several times that night, I resolved to repeat my researches the following day. But the animal being exhausted, died before the morning, and the light disappeared; and afterwards, not being able to find any more specimens, I was prevented from ascertaining the fact by reiterated experiments at different times."

PAWLE, in a ship, a small piece of iron bolted to one end of the beams of the deck, close to the capstan; but yet so easily, as that it can turn about. Its use is, to stop the capstan from turning back, by being made to catch hold of the whelps: they therefore say, heave a pawle; that is, heave a little more, for the pawle to get hold of the whelps: and this they call pawling the capstan.

PAWN, a pledge lodged for the security of the payment of a sum of money borrowed. As the party that pawns the goods has a general property therein, they cannot be forfeited by the person that has them in pawn, for any offence of his; neither can they be taken in execution for his debt: on the other hand, where goods are repawned for money, if after judgment is obtained against the pawner for debt, the goods in the pawnee's hands are not liable to execution until such time as the money lent is paid to the pawnee. He that borrows money on a pawn is to have again the pledge, when he repays the same, or he may bring an action for detaining it; and his very tender of the money revests the special property in him. Likewise it has been held, that where a broker refuses, on tendering the money, to redeliver the goods, he thereupon shall be indicted. In case goods are pawned for lent money, and no day fixed for their redemption, they are said to be redeemable at any time during the pawner's life; and though they may not be redeemed after his death, they may after the death of the pawnee. Where the pawn is redeemable on a certain day, it must be strictly observed, or upon failure of payment it may be sold. Also it is the common practice of the brokers, when no day is fixed for redemption, not to stay longer than a year for their money, at the expiration of which time they usually sell the goods. See also 39 and 40 Geo. III. c. 99.

PAY, in the sea language. The seamen say, pay more cable, when they mean to let out more cable.

PAYING, among seamen. When the seams of a ship are laid over with a coat of hot pitch, it is called paying her; and when this is done with canvas, parcelling: also when, after she is graved, and the soil burned off, a new coat of tallow and soap, or one of train-oil, rosin, and brimstone boiled together, is put on her, that is also called paying of a ship.

PAYMENT, is the consideration or purchase-money for goods, and may be made by the buyer giving to the seller the price agreed upon, either by bill or note, or by money. Where a day certain is appointed for payment, the party bound shall be allowed till the last moment of the day to pay it in, if it is an inland bill. 4 T. R. 173.

Payment of money before the day is, in law, payment at the day; for it cannot, in presumption of law, be any prejudice to him to whom the payment is made, to have his money before the time; and it appears by the party's receipt of it, that it is for his own advantage to receive it then. 5 Co. 117.

PEACE, in law, signifies a quiet and harmless behaviour towards the king and his people. The king, by his office and dignity royal, is the principal conservator of the peace within all his dominions, and may give authority to any other to see the peace kept, and to punish such as break it: hence it is usually called the king's peace. All the great officers of state are generally conservators of the peace throughout the kingdom, and may commit all breakers of it, or bind them in recognizance to keep it. Also the sheriff, coroner, constables, and tithingmen, are conservators of the peace within their own jurisdiction; and may apprehend all breakers of the peace, and commit them till they find sureties to keep the peace. 1 Black. 350.

PEACE, *justices of the*, are persons appointed by the king's commission to attend to the peace of the county where they dwell. They were called guardians of the peace till the 36th year of Edw. III. c. 12, where they are called justices.

A justice of the peace must, before he acts, take the oath of office, which is always done at the general quarter sessions for the county, by virtue of a dedimus potestatem out of chancery.

Sheriffs, coroners, attorneys, and proctors, may not act as justices of the peace.

The power, office, and duty of this magistrate, extends to an almost infinite number of instances, specified in some hundreds of acts of parliament, and every year accumulating.

The commission of the peace does not determine by the demise of the king, nor until six months after, unless sooner determined by the successor: but before his demise, the king may determine it, or may put out any particular person; which is most commonly done by a new commission, leaving out such person's name.

Justices of the peace can only be appointed by the king's special commission, and such commission must be in his name; but it is not requisite that there should be a special suit or application to, or warrant from, the king for the granting thereof, which is only requisite for such as are of a particular nature; as constituting the mayor of such a town, and his successors, perpetual justices of the peace within their liberties, &c. which commissions are neither revocable by the king, nor determinable by his demise, as the common commission of the peace is, which is made of course by the lord chancellor, according to his discretion. 1 Lev. 219.

The form of the commission of the peace, as it is at this day, was, according to Hawkins, settled by the judges about the 23 Eliz. 4 Inst. 471.

Qualifications. On renewing the commission of the peace (which generally happens when any person is newly brought into the same), a writ of dedimus potestatem is issued out of chancery to take the oath of him who is newly inserted, which is usually in a schedule annexed; and to certify the same into that court at such a day as the writ commands. Unto which oath are usually annexed the oaths of allegiance and supremacy. Lamb. 53.

Jurisdiction. It seems now to be settled, that justices of the peace have no power to hear and determine felonies, unless they are authorized so to do by the express words of their commissions; and that their jurisdictions to hear and determine murder, manslaughter, and other felonies and trespasses, is by force of the word assignavimus in their commission, which gives them, or two of them (whereof one is of the quorum), power to hear and determine felonies, &c. 2 Haw. P. C. 38. And hence it has been lately adjudged, that the caption of an indictment of trespass before justices of the peace, without adding, necnon ad diversas felonias, &c. assignat, is naught. Trin. 7 G. I. in B. R. But though justices of the peace, by force of their commission, have authority to hear and determine murder and manslaughter, yet they seldom exercise a jurisdiction herein, or in any other offences in which clergy is taken away, for two reasons: 1. By reason of the monition and clause in their commission, viz. in cases of difficulty to expect the presence of the justices of assize. 2. By the direction of the statute of 1 and 2 P. and M. c. 13, which directs justices of the peace, in case of manslaughter and other felonies, to take the examination of the prisoner, and the information of the fact, and put the same in writing; and then to bail the prisoner if there is cause, and to certify the same with the bail at the next general gaol-delivery; and therefore in cases of great moment they bind over the prosecutors, and bail the party, if bailable, to the next general gaol-delivery; but in smaller matters, as petty larceny, and in some other cases, they bind over to the sessions; but this is only in point of discretion and convenience, not because they have not jurisdiction of the crime.

As to inferior offences, the jurisdiction herein given to justices of the peace by particular statutes, is so various, and extends to such a multiplicity of cases, that it would be endless to endeavour to enumerate them. 6 Mod. 128. It has been held, that not only assaults and batteries, but libels, barratry, and common night-walking, and haunting bawdy-houses, and such like offences, which have a direct tendency to cause breaches of the peace, are cognizable by justices of the peace, as trespasses within the proper and natural meaning of the word. 1 Lev. 139.

Duty. Justices of the peace are to hold their sessions four times in the year, viz. the first week after Michaelmas, the Epiphany, Easter, and St. Thomas. They are justices of record; for none but justices of record can take a recognizance of the peace. Every justice of the peace has a separate power, and may do all acts concerning his office apart and by himself, and even may commit a fellow-justice upon treason, felony, or breach of the peace; and this is the antient power which conservators of the peace had at common law. By several statutes justices may act, in many cases, where their commission does not reach; the statutes themselves being a sufficient commission. Wood, Inst. 79, 80.

Justices of the peace are authorized to do all things appertaining to their office, so far as they relate to the laws for the relief, maintenance, and settlement of the poor; for passing and punishing vagrants; for repair of the highways; or to any other laws concerning parochial taxes, levies, or rates; notwithstanding they are rated or chargeable with the rates, with any place affected by such their acts. Provided that this shall not empower any justice for any county at large to act in the determination of any appeal to the quarter-sessions of such county, from any order, matter, or thing, relating to any such parish, township, or place, where such justice is so charged or chargeable. 16 Geo. II. c. 18.

The power of justices is ministerial, when they are commanded to do any thing by a superior authority, as the court of B. R. &c. In all other cases they act as judges; but they must proceed according to their commission, &c. Where a statute requires an act to be done by two justices, it is an established rule, that if the act is of a judicial nature, or the result of discretion, the two justices must be present to concert and join in it, otherwise it will be void; as in the orders of removal and filiation, the appointment of overseers, and the allowance of the indenture of a parish apprentice; but where the act is merely ministerial, they may act separately, as in the allowance of a poor-rate. This is the only act of two justices which has been construed to be ministerial; and the propriety of this construction has been justly questioned. 4 Durnf. & East, 386.

If a justice of the peace does not observe the form of proceeding directed by a statute, it is coram non judice, and void; but if he acts according to the direction of the statutes, neither the justices in sessions, nor B. R. can reverse what he has done. Jones, 170.

Where a justice shall exceed his authority in granting a warrant, the officer must execute it, and he is indemnified for so doing; but if it is in a case wherein he has no jurisdiction, or in a matter whereof he has no cognizance, the officer ought not to execute such warrant; for the officer is bound to take notice of the authority and jurisdiction of the justice. 10 Co. 76.

Justices acting improperly. If a justice of the peace will not, on complaint to him made, execute his office, or if he shall misbehave in his office, the party grieved may move the court of king's bench for an information, and afterwards may apply to the court of chancery to put him out of the commission. But the most usual way of compelling justices to execute their office, in any case, is by writ of mandamus out of the court of king's bench.

Where the plaintiff in an action against a justice, shall obtain a verdict, and the judge shall, in open court, certify on the back of the record, that the injury for which such action was brought, was wilfully and maliciously committed, the plaintiff shall have double costs. 24 G. II. c. 44. And if a justice of peace acts improperly, knowingly, information shall be granted. 27 G. III.

No justice shall be liable to be punished both ways, that is, criminally and civilly; but before the court will grant an information, they will require the party to relinquish his civil action, if any such is commenced: and even in the case of an indictment, and though the indictment is actually found, the attorney-general, on application made to him, will grant a noli prosequi upon such indictment, if it appears to him that the prosecutor is determined to carry on a civil action at the same time. Bur. 719.

If any action shall be brought against a justice for any thing done by virtue of his office, he may plead the general issue, and give the special matter in evidence; and if he recovers he shall have double costs. 7 Jac. c. 5. Such action shall not be laid but in the county where the fact was committed. 21 Jac. c. 12. And no suit shall be commenced against a justice of the peace till after one month's notice. And unless it is proved upon the trial that such notice was given, the justice shall have a verdict and costs. And no action shall be brought against any constable or other officer, or any person acting by his order and in his aid, for any thing done in obedience to the warrant of a justice, till demand has been made, or left at the usual place of his abode, by the party or by his attorney, in writing, signed by the party demanding the same, of the perusal and copy of such warrant, and the same has been refused or neglected for six days after such demand. And no action shall be brought against any justice for any thing done in the execution of his office, unless commenced within six months after the act committed. 24 G. II. c. 44.

PEACH, in botany. See AMYGDALUS.

PEACOCK. See PAVO.

PEAK OF DERBYSHIRE, a chain of very high mountains in the county of Derby in England, famous for the mines they contain, and for their remarkable caverns. The most remarkable of these are Pool's-hole and Elden-hole. The former is a cave at the foot of a high hill called Coitmoss, so narrow at the entrance that passengers are obliged to creep on all-fours; but it soon opens to a considerable height, extending to above a quarter of a mile, with a roof somewhat resembling that of an antient cathedral. By the petrifying water continually dropping in many parts of the cave, are formed a variety of curious figures, and representations of the works both of nature and art. There is a column here as clear as alabaster, which is called "the queen of Scots' pillar," because queen Mary is said to have proceeded thus far when she visited the cavern. It seems, the curiosity of that princess had led her thus far into the dark abode, and indeed there are few travellers who care to venture farther; but others, determined to see the end of all, have gone beyond it. After sliding down the rock a little way, is found the dreary cavity turned upwards: following its course, and climbing from crag to crag, the traveller arrives at a great height, till the rock, closing over his head on all sides, puts an end to any further subterraneous journey. Just at turning to descend, the attention is caught by a chasm, in which is seen a candle glimmering at a vast depth underneath. The guides say, that the light is at a place near Mary queen of Scots' pillar, and no less than 80 yards below. It appears frightfully deep indeed to look down; but perhaps does not measure any thing like what it is said to do. If a pistol is fired by the queen of Scots' pillar, it will make a report as loud as a cannon. Near the extremity there is a hollow in the roof, called "the needle's eye;" in which if a candle is placed, it will represent a star in the firmament to those who are below. At a little distance from this cave are two small clear streams, consisting of hot and cold water, so near each other, that the finger and thumb of the same hand may be put, the one into the hot water, and the other into the cold.

Elden-hole is a dreadful chasm in the side of a mountain; which, before the latter part of the last century, was thought to be altogether unfathomable. In the time of queen Elizabeth a poor man was let down into it for 200 yards; but he was drawn up in a frenzy, and soon after died. In 1682 it was examined by captain Collins, and in 1699 by captain Sturmy, who published their accounts in the Philosophical Transactions. The latter descended by ropes fixed at the top of an old lead-ore pit, four fathoms almost perpendicular, and thence three fathoms more obliquely, between two great rocks. At the bottom of this he found an entrance into a very spacious cavern, whence he descended along with a miner for 25 fathoms perpendicular. At last they came to a great river or water, which he found to be twenty fathoms broad and eight fathoms deep. The miner who accompanied him, insisted that this water ebbed and flowed with the sea; but the captain disproved this assertion, by remaining in the place from three hours flood to two hours ebb, during which time there was no alteration in the height of the water. As they walked by the side of this water, they observed a hollow in the rock some feet above them. The miner went into this place, which was the mouth of another cavern; and walked for about 70 paces in it, till he just lost sight of the captain. He then called to him, that he had found a rich mine, but immediately after came running out, and crying that he had seen an evil spirit; nor could any persuasions induce him to return. The floor of these caverns is a kind of white stone enamelled with lead ore, and the roofs are encrusted with shining spar. On his return from this subterraneous journey, captain Sturmy was seized with a violent head-ache, which, after continuing four days, terminated in a fever, of which he died in a short time.

Several years ago this cavern was visited by the late Mr. James Ferguson, who tells us, that it consists of two hollows one over another; but that the mouth of the lowermost is now stopped up by planks of timber laid across it, on which is a heap of stones thrown in at the upper mouth, with a design to fill up the cavern entirely; which, however, will probably be never accomplished, on account of its vast size.

PEAR, in botany. See Pyrus.

PEARCH, in ichthyology. See Perca.

PEARL, in natural history, a hard, white, shining body, usually roundish, found in various kinds of testaceous fishes.

Pearls, though esteemed of the number of gems by our jewellers, and highly valued, not only at this time, but in all ages, proceed only from a distemper in the creature that produces them, analogous to the bezoars and other stony concretions in several animals of other kinds.

The fish in which the largest and finest pearls are usually produced, is the East Indian pearl-oyster, as it is commonly called. Besides this shell there are many others that are found to produce pearls; as the common oyster, the muscle, and several others, the pearls of which are often very good; but those of the true Indian berberi, or pearl-oyster, are in general superior to all. The small or seed-pearls, also called ounce-pearls, from their being sold by the ounce and not by tale, are vastly the most numerous and common; but, as in diamonds, among the multitudes of small ones, there are smaller numbers and larger found, so in pearls there are larger and larger kinds; but as they increase in size, they are proportionably less frequent; and this is one reason of their great price. We have Scotch pearls frequently as large as a little tare, some as big as a large pea, and some few of the size of a horse-bean; but these are usually of a bad shape, and of little value in proportion to their weight. Philip II. of Spain had a pearl perfect in its shape and colour, and of the size of a pigeon's egg. The finest, and what is called the true shape of the pearl, is a perfect round; but if pearls of a considerable size are of the shape of a pear, as is not unfrequently the case, they are not less valued, as they serve for ear-rings and other ornaments. Their colour ought to be a pure white; and that not a dead and lifeless, but a clear and brilliant one: they must be perfectly free from any foulness, spot, or stain; and their surfaces must be naturally smooth and glossy; for they bring their natural polish with them, which art is not able to improve.

All pearls are formed of the matter of the shell, and consist of a number of coats spread with perfect regularity one over another, in the manner of the several coats of an onion, or like the several strata of the stones found in the bladders or stomachs of animals, only much thinner.

The manner of fishing for pearls in the East Indies is this: There are two seasons for pearl-fishing; the first is in March and April, and the last in August and September; and the more rain there falls in the year, the more plentiful are these fisheries. At the beginning of the season there are sometimes 250 barks on the banks: the larger barks have two divers, and the smaller one. As soon as barks arrive at the place where the fish lie, and have cast anchor, each diver binds a stone, six inches thick and a foot long, under his body, which serves him as a ballast, prevents his being driven away by the motion of the water, and enables him to walk more steadily under the waves. They also tie another very heavy stone to one foot, by which they are very speedily sent to the bottom of the sea: and as the oysters are usually firmly fastened to the rocks, they arm their hands with leather mittens, to prevent their being wounded in pulling them violently off; but this task some perform with an iron rake. In the last place, each diver carries down with him a large net, in the manner of a sack, tied to his neck by a long cord, the other end of which is fastened to the side of the bark. This net is to hold the oysters gathered from the rock; and the cord is to pull up the diver when his bag is full, or when he wants air. In this equipage he sometimes precipitates himself sixty feet under water; and as he has no time to lose, he no sooner arrives at the bottom, than he begins to run from side to side, tearing up all the oysters he meets with, and cramming them into his budget.

At whatever depth the divers are, the light is so great, that they easily see whatever passes in the sea; and, to their great consternation, sometimes perceive monstrous fishes, from which all their address in mudding the water, &c. will not save them, but they unhappily become their prey: and of all the dangers of the fishery this is one of the greatest and most usual. The best divers will keep under water near half an hour, and the rest do not stay less than a quarter. During this time they hold their breath, without the use of oils or any other liquors; only acquiring the habit by long practice. When they find themselves straitened, they pull the rope to which the bag is fastened, and hold fast by it with both hands; when those in the bark, taking the signal, heave them up into the air, and unload them of their fish; which is sometimes 500 oysters, and sometimes not above 50. Some of the divers need a moment's respite to recover breath; others jump in again instantly, continuing this violent exercise without intermission for several hours.

On the shore they unload their barks, and lay their oysters in an infinite number of little pits dug in the sand four or five feet square, raising heaps of sand over them to the height of a man; and in this condition they are left till the rain, wind, and sun, have obliged them to open, which soon kills them: upon this the flesh rots and dries; and the pearls, thus disengaged, fall into the pit on their taking out the shells. After clearing the pits of the grosser filth, they sift the sand several times, in order to find the pearl; but, whatever care they take, they always lose a great many. After cleaning and drying the pearls, they are passed through a kind of sieve, according to their sizes; the smallest are then sold as seed pearls, and the rest put up to auction, and sold to the highest bidder. See also Mya: and for the composition of the pearl, see the next article.

Mother-of-Pearl, is the shell not of the pearl oyster, but of another sea-fish of the oyster kind. This shell on the inside is extremely smooth, and of the whiteness and water of pearl itself; and it has the same lustre on the outside, after the first laminæ or scales have been cleared off with aquafortis, and the lapidary's mill. Mother-of-pearl is used in inlaid works, and in several toys, as snuff-boxes, &c.

Mother-of-pearl shells, when exposed to a red heat, crackle, blacken, and emit a strong fetid odour. They exfoliate, and become grey and white; when immersed in acids, they effervesce. The acids take up only the lime, and leave a number of thin membranaceous substances, which still retain the form of the shell. From Mr. Hatchett's experiments we learn, that these membranes have the properties of coagulated albumen. Mother-of-pearl shells then are composed of alternate layers of coagulated albumen and carbonat of lime, beginning with the epidermis, and ending with the last-formed membrane. The animals which inhabit these shells increase their habitation by the addition of a stratum of carbonat of lime, secured by a new membrane; and as every additional stratum exceeds in extent that which was previously formed, the shell becomes stronger as it becomes larger.

Though this in general is the structure of the mother-of-pearl shells, yet there is a considerable difference between the proportion of the component parts, and the consistency of the albuminous part. Some of them, as the common oyster-shell, approach nearly to the patellæ, the albuminous portion being small, and its consistence nearly gelatinous; while others, as the haliotis iris, the turbo olearius, the real mother-of-pearl, and a species of fresh-water muscle analysed by Hatchett, the membranes are distinct, thin, compact, and semitransparent. Mother-of-pearl contains

66	carbonat of lime
34	membrane
100.	

The pearl which is formed in some of these shells (see the preceding article) resembles them exactly in its structure and composition. It is a beautiful substance of a blueish-white colour, iridescent, and brilliant. It is composed of concentric and alternate cost a of thin membrane and carbonat of lime. Their iridescence is obviously the consequence of the lamellated structure.

Mr. Hatchett found that what is called the bone of the cuttle-fish is exactly similar to mother-of-pearl shells in its composition.

From the comparative analysis of shells and bones Mr. Hatchett was induced to compare them together, and has shewn that porcelanous shells bear a striking resemblance to enamel of teeth, while mother-of-pearl shells bear the same resemblance to the substance of teeth or bone: with this difference, that in enamel and bone the earthy salt is phosphat of lime, whereas in shells it is pure carbonat of lime.

PEARLS, *artificial*. Attempts have been made to take out stains from pearls, and to render the foul opaque-coloured ones equal in lustre to the Oriental. Abundance of processes are given for this purpose in books of secrets and travels; but they are very far from answering what is expected from them. Pearls may be cleaned indeed from any external foulnesses by washing and rubbing them with a little Venice soap and warm water, or with ground rice and salt, with starch and powder-blue, plaister of Paris, coral, white vitriol and tartar, cuttle-bone, pumice-stone, and other similar substances; but a stain that reaches deep into the substance of pearls is impossible to be taken out. Nor can a number of small pearls be united into a mass similar to an entire natural one, as some pretend.

There are, however, methods of making artificial pearls, in such a manner as to be with difficulty distinguished from the best Oriental. The ingredient used for this purpose was long kept a secret; but it is now discovered to be a fine silver-like substance found upon the under side of the scales of the blay or bleak. The scales, taken off in the usual manner, are washed and rubbed with fresh parcels of fair water, and the several liquors suffered to settle: the water being then poured off, the pearly matter remains at the bottom, of the consistence of oil, called by the French essence d'orient. A little of this is dropped into a hollow bead of blueish glass, and shaken about so as to line the internal surface; after which the cavity is filled up with wax, to give solidity and weight. Pearls made in this manner are distinguishable from the natural only by their having fewer blemishes.

PEAT, a well-known inflammable substance, used in many parts of the world as fuel. There are two species.

It consists, according to Kirwan, of clay mixed with calcareous earths and pyrites; sometimes also it contains common salt. While soft it is formed into oblong pieces for fuel, after the pyritaceous and stony matters are separated. By distillation it yields water, acid, oil, and ammonia; the ashes containing a small proportion of fixed alkali; and being either white or red, according to the proportion of pyrites contained in the substance.

The oil which is obtained from peat has a very pungent taste, and an empyreumatic smell, less fetid than that of animal substances, but more so than that of mineral bitumens: it congeals in the cold into a pitchy mass, which liquefies in a small heat: it readily catches fire from a candle, but burns less vehemently than other oils, and immediately goes out upon removing the external flame: it dissolves almost totally in rectified spirit of wine into a dark brownish-red liquor.

It is evident that peat will vary as to composition, according to situation and circumstance; and in almost every place will be found somewhat different. The following is an account of the peat found near Newbury in Berkshire: It is a composition of the branches, twigs, leaves, and roots of trees, with grass, straw, and plants, particularly moss, which, having lain long in water, is formed in a mass so soft as to be cut through with a sharp spade. The colour is a blackish brown, and it is used in many places for firing. There is a stratum of this peat on each side of the Kennet, near Newbury in Berks, which is from about a quarter to half a mile wide, and many miles long. The depth below the surface of the ground is from one foot to eight. Great numbers of entire trees are found lying irregularly in the true peat. They are chiefly oaks, alders, willows, and firs, and appear to have been torn up by the roots: many horses' heads, and bones of several kinds of deer; the horns of the antelope, the heads and tusks of boars, and the heads of beavers, are also found in it. Not many years ago an urn of a light-brown colour, large enough to hold about a gallon, was found in the peat-pit in Speen moor, near Newbury, at about 10 feet from the river, and four feet below the level of the neighbouring ground. Just over the spot where the urn was found, an artificial hill was raised about eight feet high; and as this hill consisted both of peat and earth, it is evident that the peat was older than the urn. From the side of the river several semicircular ridges are drawn round the hill, with trenches between them. The urn was broken to shivers by the peat-diggers who found it, so that it could not be critically examined; nor can it be known whether any thing was contained in it.

The ashes, properly burnt, are advantageously used for a manure. See HUSBANDRY.

There are many low grounds, which, nearly on a level with small rivers, and sometimes even below it, are alternately covered with earth and left by their waters, or admit them in such a manner as to be continually fermented by them. These grounds producing an enormous quantity of plants crowded together, incessantly growing, and annually accumulating layer upon layer, their soil becomes loaded to a greater or less depth with remains of vegetables, or herbaceous stalks, interwoven with each other in all directions, of a black and coaly colour, and of a disagreeable or even fetid smell, which indicate a considerably advanced stage of vegetable decomposition.

These remains, still solid and combustible, are known by the name of turf or peat; and the place from which they are taken are called bogs. Though peat consists of coherent masses, belonging to a much larger mass of one single piece of a subterranean deposit, yet by separating the filaments which compose their texture, we may distinguish several of the plants which have contributed to their formation. They are separable into long, soft, brown, or black stalks, sometimes indeed of a blueish or violet colour, which have lost the natural consistence of the plants to which they belonged, and are manifestly altered in their texture as well as in their nature.

When turf is heated in an apparatus for distillation, we obtain from it a yellow or reddish fetid water, an extremely stinking oil, carbonate of ammonia, and carbonated hydrogen gas of a very disagreeable smell. The residuum is a coal, frequently pyrophoric, from which some salts may be extracted after incineration; particularly muriates and sulphates of soda and potass, mixed with phosphate of lime, calcareous sulphate, and oxides of iron and manganese. Every person knows the manner in which turf burns in fire-places and furnaces, the ill smell it emits, and the reddish ferruginous ashes it leaves. Attempts have been made with some success to divest it of these inconveniences, by half-burning it in close vessels, so as to char it like wood. This process has certainly its advantage. It must be mentioned, however, that this charcoal is inferior to that commonly made from wood; and that it is liable to take fire from the combined action of air and water, so that it ought to be kept for use in close places well secured.

Peat therefore is in reality the residuum of plants or herbs half-decomposed, half-burned, reduced almost to the state of charcoal, analogous in its nature to fossil wood, which is equally carbonaceous. It is used as fuel, where there is no other. It may be very useful in forges: its ashes are employed as manure. By lixiviation, salts of use in the arts may be obtained from it. There are some bogs which are found to contain likewise sulphuret of iron, or pyrites. This compound, so combustible in moist air, heats them when they are exposed to it, and even occasions them to take fire. Some of them, such as those in the environs of Beauvais, are even capable of furnishing by lixiviation sulphate of iron, which is formed in them by exposure to the air. There is no doubt that most peats may be employed for obtaining from them by distillation an oil analogous to tar, as Becher proposed in 1683.

PEBBLES, the name of a genus of fossils, distinguished from the flints by having a variety of colours. These are defined to be stones composed of a crystalline matter debased by earths of various kinds in the same species; and then subject to veins, clouds, and other variegations, usually formed by incrustation round a central nucleus, but sometimes the effect of a simple concretion; and veined like the agates, by the disposition which the motion of the fluid they were formed in gave their differently-coloured substances.

The variety of pebbles is so great, that a hasty describer would be apt to make almost as many species as he saw specimens. A careful examination will teach us, however, to distinguish them into a certain number of essentially different species, to which all the rest may be referred as accidental varieties. When we find the same colours, or those resulting from a mixture of the same, such as nature frequently makes in a number of stones, we shall easily be able to determine that these are all of them the same species, though of different appearances; and this whether the matter is disposed of in one or two, or in 20 crusts, laid regularly round a nucleus; or thrown irregularly, without a nucleus, into irregular lines; or, lastly, if blended into an uniform mass.

These are the three states in which every pebble is found; for if it has been naturally and regularly formed by incrustation round a certain nucleus, we find that always the same in the same species, and the crusts not less regular and certain. If the whole has been more hastily formed, and the result only of one simple concretion, if that has happened while its different substances were all moist and thin, they have blended together and made a mixed mass of the joint colour of them all. But if they have been something harder when this has happened, and too far concreted to diffuse wholly among one another, they are found thrown together into irregular veins. These are the natural differences of all the pebbles; and having regard to these in their several variegations, all the known pebbles may be reduced to 34 species.

Such pebbles as are found in strata near the surface of the earth, are much more brittle than those which lie in deeper strata; and the more clear and transparent the sand is which is found among pebbles, the more beautiful the pebbles are generally observed to be.

PENCHBLENDE, one of the ores of uranium. See URANIUM.

PECORA, in zoology, the fifth order of the class mammalia, in the Linnæan system: they are thus distinguished; fore-teeth upper, none; lower, cutting, many; feet hoofed, cloven; food herbs, which they pluck; chew the cud; stomachs four; the paunch to macerate and ruminate the food; the bonnet, reticulate, to receive it; the omasus, or maniples of numerous folds, to digest it; and the abomasus or caille, fasciate, to give it acescency, and prevent putrefaction. In this order there are eight genera, viz. the antelope, bos, camelopardalis, camelus, capra, cervus, moschus, and ovis.

PECTEN, the *scallop*; a genus of shellfish, the characters of which are these: the animal is a tethys; the shell bivalve and unequal; the hinge toothless, having a small ovated hollow. This shell-fish is one of the spinners, having the power of spinning threads like the muscles; but they are much shorter and coarser than even those of that fish, so that they can never be wrought into any kind of work like the longer and finer threads of the pinna marina. The use of the threads which are spun by the scallop is, to fix the creature to any solid body near its shell. All these proceed, as in the muscle, from one common trunk. It is an evident proof that the fish has a power of fixing itself at pleasure to any solid body by means of these threads, that after storms the scallops are often found tossed upon rocks, where there were none the day before; and yet these are fixed by their threads, as well as those which had remained ever so long in their place. They form their threads in the very same manner with the muscle; only their organ which serves for spinning is shorter, and has a wider hollow, whence the threads are necessarily thicker and shorter.

The pectens, such as the sole pecten, the ducal-mantle pecten, the knotted, and others, seem to be in general inhabitants of the Indian seas; some of them frequent those of Africa, and the South seas. The most remarkable species is the maximus or great scallop, being the same with what Barbut calls the ducal-mantle pecten. It has fourteen rays, very prominent and broad, and striated both above and below. They are rugged, and imbricated with scales. They grow to a large size, are found in beds by themselves, are dredged up, and barrelled for sale. The antients say that they have a power of removing themselves from place to place by vast springs or leaps. This fish was used both by the Greeks and Latins as a food. When dressed with pepper and cummin, it was taken medicinally. The scallop was commonly worn by pilgrims on their hat, or the cape of their coat, as a mark that they had crossed the sea in their way to the Holy Land, or some distant object of devotion.

PECTIS, a genus of the class and order syngenesia polygamia superflua. The cal. is five-leaved, cylindric; florets in the ray five; down awned; recept. naked. There are four species, annuals of the West Indies.

PECULIAR, in the canon law, signifies a particular parish or church that has jurisdiction within itself for granting probates of wills, and administrations, exempt from the ordinary or bishop's courts. The king's chapel is a royal peculiar, exempt from all spiritual jurisdiction, and reserved to the visitation and immediate government of the king himself. There is likewise the archbishop's peculiar; for it is an antient privilege of the see of Canterbury, that wherever any manors or advowsons belong to it, they forthwith become exempt from the ordinary, and are reputed peculiars; there are fifty-seven such peculiars in the see of Canterbury. Besides these, there are some peculiars belonging to deans, chapters, and prebendaries, which are only exempted from the jurisdiction of the archdeacon; these are derived from the bishop, who may visit them, and to whom there lies an appeal.

PEDALS. See ORGAN.

PEDALIUM, a genus of the class and order didynamia angiospermia. The cal. is five-parted; the cor. five-cleft; nect. subaceous; seeds two. There is one species, an annual of the East Indies.

PEDESTAL. See ARCHITECTURE.

PEDICELLARIA, a genus of insects, of the order vermes mollusca: the generic character is, body soft and seated on a rigid peduncle; aperture single. There are three species. The P. tridens inhabits the north seas, among the spines of echini: nect. smooth, hyaline, sometimes reddish; lobes of the head sometimes four, and three times as long as the neck, rarely unarmed with awn; peduncle reddish, and three times as long as the neck. See Plate Nat. Hist. fig. 319.

PEDICULARIS, *red-rattle*, or *lousewort*, a genus of the didynamia angiospermia class of plants, the corolla whereof consists of a single ringent petal; the tube is oblong and gibbous; the upper lip galeated, erect, compressed, and emarginated; the under one is patent, plane, semitrifid, and obtuse; the fruit is a roundish acuminated capsule; the seeds are numerous, roundish, compressed and covered. There are 19 species. This plant is of a cooling and drying nature, whence it is recommended in fistulas and other sinous ulcers. It also stops hæmorrhages and the menses.

PEDICULUS, louse, a genus of insects of the order aptera: the generic character is, legs six, formed for walking; mouth furnished with an exsertile piercer; antennæ the length of the thorax; abdomen depressed, sublobated.

This is a very numerous genus of insects, far more remarkable for variety than elegance of appearance. Of these strange and unpleasing animals some infest the bodies of quadrupeds, others of birds, and some even those of insects themselves. It must, however, be here observed, that many small insects, infesting other animals, have been often referred to the genus pediculus, which in reality belong to those of acarus, monoculus, &c. &c.

The pediculus humanus, or common louse, is so well known as to render any particular description unnecessary. As a species, it is distinguished by its pale livid colour, and lobated, oval abdomen. It is produced from a small oval egg, properly called by the name of a nit, which is fastened or agglutinated by its smaller end to the hair on which it is deposited. From this egg proceeds the insect, complete in all its parts, and differing only from the parent animal in its smaller size. Such diminutive specimens are far preferable, for microscopic observation, to the full-grown insects, shewing in a more distinct manner the disposition of the viscera, muscles, &c. &c. When thus examined by the microscope, the principal appearances are as follow, viz. The trunk or proboscis, which is generally concealed in its sheath or tube, is of a very sharp form, and is furnished towards its upper part with a few reversed aculei or prickles; the eyes are large, smooth, and black: the stomach and intestines, which possess the greater part of the abdominal cavity, afford an extremely distinct and curious view of the peristaltic motion; while the ramifications of the tracheæ, or respiratory tubes, appear dispersed in an elegant manner throughout various parts of the animal, and are particularly observable towards their orifices on the sides of the abdomen; the legs are each terminated by a double claw, not greatly unlike that of a lobster, but of a much sharper form; and the whole animal is every where covered by a strong granulated skin. It is affirmed by Lewenhoek, that the male is furnished at the extremity of the abdomen with a sting, and that it is this extremity which causes the chief irritation suffered from these animals; the suction of the proboscis hardly seeming to have caused any perceptible pain on the skin of his hand. The male is readily distinguished from the female by having the tail or tip of the abdomen rounded; in the female it is forked or bifid. The same accurate observer (Lewenhoek), being desirous of learning the proportion and time of the increasing of these insects, placed two females in a black silk stocking, which he wore day and night for that purpose. He found that in six days, one of them had laid fifty eggs, and upon dissecting it, he found as many more in the ovary; he therefore concluded that in twelve days it would have laid a hundred eggs; these eggs, hatching in six days, which he found to be their natural time, would probably produce fifty males and as many females; and these females coming to their full growth in eighteen days, might each of them be supposed, after twelve days more, to lay also a hundred eggs; which in six days farther (the time required to hatch them) might produce a younger brood of five thousand; so that in eight weeks a louse might see five thousand of its own descendants.

The louse, in all ages enumerated among the pests of mankind, has been sometimes represented as the mere punishment of personal negligence, and sometimes commemorated as one of the most humiliating concomitants of degraded pride; since, exclusive of the memorable and impressive descriptions on this subject in the sacred writings, we meet with various examples of characters of no small degree of eminence who have suffered from the attacks of this odious insect. The disorder, however, commonly termed phthiriasis, is probably more owing to want of attention during the first stages of its appearance, than to any real constitutional cause in the patient; it being entirely contrary to the nature of this insect to get under the cuticle, as commonly supposed; and utterly inconceivable that a complaint merely external should be able to resist mercurial or other preparations outwardly used; there can be little doubt that such cases, whenever they occur, would be effectually removed by a proper application of a dilute solution of mercury sublimate. We must even venture to express our doubts whether a real and genuine phthiriasis, considered as a primary disease, has ever appeared. Notwithstanding this, we are told by Pliny that Pherecydes Sirius, Sylla the dictator, and others, have died of this disorder.

The insects of this genus found on quadrupeds and birds, may be considered as almost equalling the number of the animals themselves; since few of either division exist without one or more species peculiar to themselves.

PEDIGREE. See Descent.

PEDIMENT. See Architecture.

PEDOMETER, or Podometer, foot-measurer, or way-wiser; a mechanical instrument, in form of a watch, and consisting of various wheels and teeth; which, by means of a chain, or string, fastened to a man's foot, or to the wheel of a chariot, advance a notch each step, or each revolution of the wheel; by which it numbers the paces or revolutions, and so the distance from one place to another.

Plate Pedometer, &c. figs. 1, 2, 3, explains one of Spencer and Perkins's pedometers or way-wisers, which when worked in the pocket ascertains the number of steps made by the wearer. The external appearance, fig. 1. is somewhat like that of a watch: in the place of the watch-chain is a brass lever A, figs. 1 and 3, one end of which is bent into a hook; the other has a hole *a* through it, as shewn in fig. 2, and has a cleft cut in it through the hole; through this hole a wire passes, which wire is fixed between the two studs *b b*, figs. 1 and 2, so as to turn round freely; it also goes through the two arms of the piece B, fig. 2, and is made fast to them so that they turn with it the arm *x*, which is higher than the other, and has a narrow opening cut in it, into which is jointed a piece of steel D by a pin through its top; the end of the lever A has two small screws in it so as to close up the hole *a*, and pinch the wire which passes through the hole tight. When the lever A is moved backwards and forwards, it turns the wire by friction, and moves the piece B up or down till it is stopped by its leaf *d* coming either against the under side of the dial, or against the back of the case, as shewn in fig. 3.; the lever then slips round the pin. When the piece B is moved up or down, it pushes or pulls the piece D in or out of the case: the end of this is in two branches *ef*; the latter ends in the plain point, the other is bent into a hook; these branches take on each side of a small racket wheel, in fig. 3, which has 10 teeth. When the lever A is moved so as to draw back the piece D, the hook *e* takes one of the teeth of the racket wheel *n*, and moves it round one tooth: at the same time the point *f* slips over the sloping side the opposite tooth, and when the piece D is pushed in, it also moves the wheel round one tooth in the same direction as while the hoof *e* slips over the teeth ready for the next movement. The racket *m* has a pinion of 6 teeth on its under side, which tacks into a wheel *n* of 60 teeth; on the spindle of this wheel (which projects through the dial), is fastened the long hand *i*, fig. 1. As the wheel *m* makes one revolution for ten strokes of the lever A, and its pinion has one-tenth of the number of teeth in the wheel *n*, it is evident that 100 strokes of the lever will be required for one revolution of the wheel *n*, and hand *i*. The wheel *n* has a pinion of six leaves on it, which gives motion to a wheel *o* of 60 teeth, which turns *r* of 60 teeth, on whose arbour the hand *t*, fig. 1. is fastened: the wheel *o* has a pinion of 6 leaves on the under side of it, which moves a wheel *y* of 72 teeth, which carries the hand *s*, fig. 1.; by this arrangement the hand *t* will turn once round for 1000 strokes of the lever A; its dial is divided into 10 each, answering to 100, or 1 revolution of the hand *i*. The index *s* will turn round once for 1200 strokes of the lever; and its circle is divided into 12 parts, each of which denotes one revolution of the hand *t*, or 100 strokes of the lever; the hands are not fastened to their spindle, but can be turned round to set them all to O when it is going to be used. The best method of placing the machine, is with a case upon the thigh, the lever A brought towards the button of the waistband, and if possible, the joints of the lever over the joints of the thigh; that the lever being over the belly is at rest, while the motion of the thigh moves the case part of the machine at every step. Set all the hands to O; and when 100 paces are walked, the long hand will have made one revolution, and the hand will move to the figure 1, and so on as before described. Persons of middle stature are found to make about 1000 paces in a mile; but it is best to walk a mile several times, observing each time by the machine, the number of paces each time, and the average of these will serve to calculate by.

PEEK, in the sea-language, is a word used in various senses. Thus the anchor is said to be a-peek, when the ship being about to weigh, comes over her anchor in such a manner that the cable hangs perpendicularly between the hawse and the anchor. To heave a-peek, is to bring the peek so that the anchor may hang a-peek. A ship is said to ride a-peek, when lying with her main and fore-yards hoisted up, one end of her yards is brought down to the shrouds, and the other raised up on end; which is chiefly done when she lies in rivers, lest other ships falling foul of the yards should break them. Riding a broad peek, denotes much the same, excepting that the yards are only raised to half the height. Peek is also used for a room in the hold, extending from the bits forward to the stem: in this room men of war keep their powder, and merchantmen their victuals.

PEERS, in our common law, are those who are impannelled in an inquest upon any man, for the convicting or clearing him of any offence, for which he is called in question; and the reason is, because the course and custom of our nation is, to try every man in such a case by his equals, or peers.

Peers *of the realm*, are the nobility of the kingdom, and lords of parliament; who are divided into dukes, marquises, earls, viscounts, and barons; and the reason why they are called peers is, because notwithstanding there is a distinction of dignities in our nobility, yet in all public actions they are equal, as in their votes of parliament, and in passing upon the trial of any nobleman.

It seems clearly, that the right of peerage was originally territorial; that is, annexed to lands, houses, castles, &c.; the proprietors and possessors of which were, in right of those estates, allowed to be peers of the realm, and were summoned in parliament to do suit and service to their sovereign; and, when the land was alienated, the dignity passed with its appendant. Thus the bishops still sit in the house of lords, in right of succession to certain ancient baronies annexed, or supposed to be annexed, to their episcopal lands. But afterwards, as alienations grew frequent, the dignity of peerage was confined to the lineage of the party ennobled; and instead of territorial, became personal. Actual proof of a tenure by barony became no longer necessary to constitute a lord of parliament; but the record of the writ of summons to him, or his ancestors, was admitted as a sufficient evidence of the tenure.

Peers are now created either by writ, or patent; for those who claim by prescription must suppose either a writ or patent made to their ancestors, though by length of time it may be lost. The creation by writ or the king's letter, is a summons to attend the house of peers, by the style and title of that barony which the king is pleased to confer; that by patents is a royal grant to a subject, of any dignity and degree of peerage. The creation by writ, is the more antient way; but a man is not ennobled by it unless he actually takes his seat in the house of lords; and therefore the most usual, because the surest way, is to grant the dignity by patent, which ensures to a man and his heirs, according to the limitations thereof, though he never himself makes use of it. 1 Black. 399.

In criminal cases, a nobleman is tried by his peers. Peers shall have the benefit of clergy for the first offence of felony without being burned in the hand.

PEERESS, a woman who is noble by descent, creation or marriage. If a peeress by descent or creation, marries a person under the degree of nobility, she still continues noble; but if she obtains that dignity only by marriage, she loses it, on her afterwards marrying a commoner; yet, by the curtesy of England, she retains the title of her nobility. No peeress can be arrested for debt or trespass; for though on account of their sex, peeresses cannot sit in the house of lords, yet they enjoy the privileges of peers, and therefore all peeresses by birth are to be tried by their peers.

PEGANUM, *wild-rue*, or *harmel*, a genus of the dodecandria monogynia class of plants, the flower of which consists of five oval petals; and its fruit is a trilocular capsule containing a great many small seeds. There are two species.

This herb is said to have an inebriating and soporific quality.

PEGASUS, in astronomy, a constellation of the northern hemisphere, in form of a flying horse; said by different authors to contain 19, 20, and 93 stars.

Pegasus is also a genus of fishes of the order nantes: the generic character is, snout elongated, mouth beneath; pectoral fins large, ventral single-rayed; body depressed, mailed, with the abdomen divided into bony segments.

Pegasus draco, dragon pegasus. The principal species of this genus, the pegasus draco, is a small fish of about the length of three or four inches, and is remarkable for the size of its pectoral fins, which are supposed to enable it, like the exocœti and some other fishes, to support itself for some moments in the air, while it springs occasionally over the surface of the water: the thorax or superior part of the body is of a broad, slightly flattened, squarish form, and is marked both above and beneath by several radiated shields or bony tubercles of considerable size; from each side of the abdomen springs a lengthened cirrus, which may be considered as supplying the place of a ventral fin; from the thorax the body decreases suddenly in diameter, and is marked into several divisions or transverse segments; the tail is small and slightly rounded; the pectoral fins, as before observed, are large in proportion to the size of the animal, and of a rounded shape, with a kind of scalloped or indented outline; the eyes are large and protuberant, and the snout of a subconical form, but with a slight dilatation towards the tip, so as to appear spatule-shaped when viewed from above; the colour of the whole animal is whitish, with a slight cast of pale brown. It is a native of the Indian seas. See Plate Nat. Hist. fig. 320.

2. Pegasus volans: length about three inches; snout much elongated; on the head a rhomboidal depression, and behind it two deep subpentagonal cavities; last joints of the body, next the tail, pointed on each side. Native of the Indian seas.

3. Pegasus natans: length three or four inches; shape much more slender than that of the P. volans; colour yellowish-brown, whitish beneath. Native of the Indian seas.

PELAGIANS, a Christian sect who appeared before the latter part of the fourth, or the beginning of the fifth century. Pelagius, the author of this sect, was born in Wales, and his name was Morgan, which in the Welsh language signfies sea-born; whence he had his Latin name Pelagius. St. Austin gives him the character of a very pious man, and a Christian of no vulgar rank: according to the same father, he travelled to Rome, where he associated himself with persons of the greatest learning and figure, and wrote his commentaries on St. Paul's espistles, and his letters to Melania and Demetrius; but being charged with heresy, he left Rome, and went into Africa, and thence to Jerusalem, where he settled. He died somewhere in the East, but where is uncertain. He was charged with maintaining the following doctrines: 1. That Adam was by nature mortal, and whether he had sinned or not, would certainly have died. 2. That the consequences of Adam's sin were confined to his own person. 3. That new-born infants are in the same condition with Adam before the fall. 4. That the law qualified men for the kingdom of heaven, and was founded upon equal promises with the gospel. 5. That the general resurrection of the dead does not follow in virtue of our Saviour's resurrection. 6. That the grace of God is given according to our merits. 7. That this grace is not granted for the performance of every moral act; the liberty of the will, and information in points of duty, being sufficient, &c. Pelagius's sentiments were condemned by several councils in Africa, and by a synod at Antioch.

There was also a sect of semi-pelagians; who, with the orthodox, allowed of original sin; but denied that the liberty of the will could be so far impaired thereby, that men could not of themselves do something which might induce God to afford his grace to one more than another; and as to election, they held, that it depended on our perseverance; God choosing only such to eternal life, as continued stedfast in the faith.

PELECOIDES, in geometry, a figure in form of a hatchet: such is the figure BCDA, (see Plate Miscel. fig. 182.) contained under the two inverted quadrantal arcs AB and AD, and the semicircle BCD. The area of the pelecoides is demonstrated to be equal to the square AC, and that again to the parallelogram EB. It is equal to the square AC, because it wants of the square on the left hand the two segments AB and AC, which are equal to the two segments BC and CD, by which it exceeds on the right hand.

PELICAN, in chemistry, a kind of double glass vessel, used in distilling liquors by circulation: it consists of a cucurbit and alembic head, with two tubes bending into the cucurbit again.

PELICANUS, in ornithology, a genus belonging to the order of anseres. The bill is straight, without teeth, and crooked at the point; the face is naked; and the feet are palmated. See Plate Nat. Hist. fig. 321. Mr. Latham enumerates no less than 30 different species of this genus, besides varieties. The most remarkable seem to be these that follow:

1. The carbo, or cormorant, sometimes exceeds seven pounds in weight; the length three feet four; the extent four feet two; the bill dusky, five inches long, destitute of nostrils; the base of the lower mandible is covered with a naked yellow skin, that extends under the chin, and forms a sort of pouch; a loose skin of the same colour reaches from the upper mandible round the eyes and angles of the mouth; the head and neck are of a sooty blackness, but under the chin of the male the feathers are white; and the head in that sex is adorned with a short, loose, pendant crest; in some the crest and hind part of the head are streaked with white. The coverts of the wings, the scapulars, and the back, are of a deep green, edged with black, and glossed with blue; the quill-feathers and tail dusky; the legs are short, strong, and black; the middle claw serrated on the inside; the irides are of a light ash-colour.

The birds occupy the highest parts of the cliffs that impend over the sea: they make their nests of sticks, sea-tang, grass, &c. and lay six or seven white eggs of an oblong form. In winter they disperse along the shores, and visit the fresh waters, where they make great havock among the fish. They are remarkably voracious, having a most sudden digestion, promoted by the infinite quantity of small worms that fill their intestines. The cormorant has the rankest and most disagreeable smell of any bird, even when alive. Its form is disagreeable, its voice hoarse and croaking, and its qualities base. These birds, however, have been trained to fish, as falcons to fowl. Whitelock tells us, that he had a cast of them manned like hawks, and which would come to hand. He took much pleasure in them; and relates, that the best he had was one presented him by Mr. Wood, master of the cormorants to Charles I. It is well known that the Chinese make great use of these birds, or a congenerous sort, in fishing; and that not for amusement, but profit.

2. The graculus, or shag, is much inferior in size to the cormorant; the length is 27 inches; the breadth three feet six; the weight three pounds and three quarters. The bill is about four inches long, and more slender than that of the preceding; the head is adorned with a crest two inches long, pointing backward; the whole plumage of the upper part of this bird is of a fine and very shining green; the edge of the feathers a purplish black; but the lower part of the back, the head, and the neck, wholly green; the belly is dusky; the tail of a dusky hue, tinged with green; the legs are black, and like those of the cormorant. Both these kinds agree in their manners, and breed in the same places; and what is very strange in web-footed birds, will perch and build in trees; both swim with their head quite erect, and are very difficult to be shot; for, like the grebes and divers, as soon as they see the flash of a gun, they pop under water, and never rise but at a considerable distance.

3. The bassanus, gannet, or solan goose, weighs seven pounds; the length is three feet one inch; the breadth six feet two inches. The bill is six inches long, straight almost to the point where it inclines down; and the sides are irregularly jagged, that it

may hold its prey with more security; it has no nostrils, but in their place a long furrow, that reaches almost to the end of the bill; the whole is of a dirty white, tinged with ash-colour.

From the corner of the mouth is a narrow slip of black bare skin, that extends to the hind part of the head; beneath the chin is another, that, like the pouch of the pelican, is dilatable, and of size sufficient to contain five or six entire herrings; which in the breeding season it carries at once to its mate or its young.

The young birds, during the first year, differ greatly in colour from the old ones; being of a dusky hue, speckled with numerous triangular white spots; and at that time resemble in colour the speckled diver. Each bird, if left undisturbed, would only lay one egg in the year; but if that is taken away, they will lay another; if that is also taken, then a third, but never more that season. The egg is white, and rather less than that of the common goose; the nest is large, and formed of any thing the bird finds floating on the water, such as grass, sea-plants, shavings, &c. These birds frequent the isle of Alisa, in the frith of Clyde; the rocks adjacent to St. Kilda; the Stalks of Souliskerry, near the Orkneys; the Skelig isles off the coasts of Kerry, Ireland; and the Bass isle in the frith of Forth: the multitudes that inhabit these islands are prodigious.

4. The sulla, or booby, is somewhat less than a goose. The colours of the body are brown and white; but varied so in different individuals, that they cannot be described by them. Their wings are very long; their legs and feet pale yellow, shaped like those of cormorants. They frequent the Bahama islands, where they breed all months in the year, laying one, two, or three eggs on the bare rock. While young, they are covered with a white down, and continue so till they are almost ready to fly. They feed on fish like the rest of this genus; but have a very troublesome enemy in the man-of-war bird, which lives on the spoils obtained from other sea-birds, particularly the booby. As soon as this rapacious enemy perceives that the booby has taken a fish, he flies furiously at him, upon which the former dives to avoid the blow; but as he cannot swallow his prey below water, he is soon obliged to come up again with the fish in his bill as before, when he suffers a new assault; nor does his enemy cease to persecute him till he lets go the fish, which the other immediately carries off.

5. The aquilus, or man-of-war bird, is in the body about the size of a large fowl; in length three feet, and in breadth fourteen. The bill is slender, five inches long, and much curved at the point; the colour is dusky; from the under mandible hangs a large membranaceous bag attached some way down the throat, as in the pelican, and applied to the same uses; the colour of this is a fine deep red, sprinkled on the sides with a few scattered feathers; the whole plumage is brownish black, except the wing-coverts, which have a rufous tinge; the tail is long and much forked; the outer feathers are eighteen inches or more in length, the middle ones from seven to eight; the legs are small, all the toes are webbed together, and the webs are deeply indented; the colour of them is dusky red.

The frigate-pelican, or man-of-war bird, as it is by some called, is chiefly, if not wholly, met with between the tropics, and ever out at sea, being only seen on the wing. Sometimes it soars so high in the air as to be scarcely visible, yet at other times approaches the surface of the sea, where, hovering at some distance, the moment he spies a fish he darts down on it with the utmost rapidity, and seldom without success, flying upwards again as quick as he descended. It is also seen to attack gulls and other birds which have caught a fish, when it obliges them to disgorge it, and then takes care to seize it before it falls into the water.

6. The onocrotalus, or pelican of Asia, Africa, and America; though Linnæus thinks that the pelican of America may possibly be a distinct variety. This creature, in Africa, is much larger in the body than a swan, and somewhat of the same shape and colour. Its four toes are all webbed together, and in some measure resemble those of a swan; but that singularity in which it differs from all other birds is in the bill, and the great pouch underneath. This enormous bill is 15 inches from the point to the opening of the mouth, which is a good way back behind the eyes. At the base the bill is somewhat greenish, but varies towards the end, being of a reddish blue. It is very thick in the beginning, but tapers off to the end, where it hooks downwards. The under chap is still more extraordinary; for to the lower edges of it hangs a bag, reaching the whole length of the bill to the neck, which is said to be capable of containing 15 quarts of water. This bag the bird has the power of wrinkling up into the hollow of the under chap; but by opening the bill, and putting the hand down into the bag, it may be distended at pleasure. The first thing the pelican does in fishing is, to fill up the bag; and then it returns to digest its burden at leisure. Tertre affirms, that it will hide as many fish as will serve 60 hungry men at a meal.

This pelican was once also known in Europe, particularly in Russia; but it seems to have deserted our coasts. This is the bird of which so many fabulous accounts have been propagated; such as its feeding its young with its own blood, and its carrying water into the desert for them in its great reservoir. But the absurdity of the first account answers itself; and as for the latter, the pelican uses its bag for very different purposes than that of filling it with water.

The pelican feeds her young with fish macerated for some time in her bag, and when they cry, flies off for a new supply. Labat tells us, that he took two of these when very young, and tied them by the leg to a post stuck in the ground, where he had the pleasure of seeing the old one for several days come to feed them, remaining with them the greatest part of the day, and spending the night on the branch of a tree that hung over them. By these means they were all three become so familiar, that they suffered themselves to be handled; and the young ones very kindly accepted whatever fish he offered them. These they always put first into their bag, and then swallowed at their leisure.

It seems, however, that they are but disagreeable and useless domestics; their gluttony can scarcely be satisfied; their flesh smells very rancid, and tastes a thousand times worse than it smells. The native Americans kill vast numbers; not to eat, for they are not fit even for the banquet of a savage, but to convert their large bags into purses and tobacco-pouches. They bestow no small pains in dressing the skin with salt and ashes, rubbing it well with oil, and then forming it to their purpose. It thus becomes so soft and pliant, that the Spanish women sometimes adorn it with gold and embroidery, to make work-bags of.

PELLICLE, among physicians, &c. denotes a thin film, or fragment of a membrane.

When any liquor is evaporated in a gentle heat, till a pellicle arises at top, it is called an evaporation to a pellicle; wherein there is just liquor enough left, to keep the salts in fusion.

PELTARIA, a genus of the siliculosa order, in the tetradynamia class of plants; and in the natural method ranking under the 39th order, siliquosæ. The silicula is entire, and nearly orbiculated, compressed plane, and not opening. There are two species, herbs of the Cape.

PELVIS, in anatomy, the lower part of the cavity of the abdomen, thus called from its resemblance to a bason, or ewer, in Latin called pelvis. See Anatomy.

PEN, *fountain*, is a pen made of silver, brass, &c. contrived to contain a considerable quantity of ink, and let it flow out by gentle degrees, so as to supply the writer a long time without being under the necessity of taking fresh ink. The fountain-pen is composed of several pieces, as in the plate, where the middle piece F carries the pen, which is screwed into the inside of a little pipe, which again is soldered to another pipe of the same bigness as the lid G; in which lid is soldered a male screw, for screwing on the cover, as also for stopping a little hole at the place, and hindering the ink from passing through it. At the other end of the piece F is a little pipe, on the outside of which the top-cover H may be screwed; In the cover there goes a port-crayon, which is to be screwed into the last-mentioned pipe, in order to stop the end of the pipe, into which the ink is to be poured by a funnel. To use the pen, the cover G must be taken off, and the pen a little shaken, to make the ink run more freely.

PENANCE, in our canon law, is an ecclesiastical punishment chiefly adjudged to the sin of fornication. The punishment is thus described by the canons: the delinquent is to stand in the church porch on some Sunday, bare-headed and barefoot, in a white sheet, with a white wand in his hand, bewailing himself, and begging every one to pray for him; then he is to enter the church, and falling down, is to kiss the ground; and at last is to be placed on an eminence in the middle of the church, over against the minister, who is to declare the foulness of his crime which is odious to God, and scandalous to the congregation. If the crime is not notorious, the canons allow the punishment to be commuted at the party's request for a pecuniary mulct, for the benefit of the poor, &c.

PENÆA, a plant of the tetrandria monogynia class, with a monopetalous campaniform flower; and a quadragonal capsule for its fruit, containing four cells, with two oblong seeds in each. There are nine species. This plant has been erroneously supposed to have produced the sarcocolla of the shops.

PENDANT, an ornament hanging at the ear, frequently consisting of diamonds, pearls, and other precious stones.

PENDANTS, in heraldry, parts hanging down from the label, to the number of three, four, five, or six at most, resembling the drops in the Doric frieze.

PENDANTS of a ship, are those streamers or long colours which are split and divided into two parts ending in points, and hung at the head of masts, or at the yard-arm ends.

PENDULUM, in mechanics, any heavy body, so suspended as that it may swing backwards and forwards, about some fixed point, by the force of gravity.

These alternate ascents and descents of the pendulum, are called its oscillations, or vibrations; each complete oscillation being the descent from the highest point on one side, down to the lowest point of the arch, and so on, up to the highest point on the other side. The point round which the pendulum moves, or vibrates, is called its centre of motion, or point of suspension; and a right line drawn through the centre of motion, parallel to the horizon, and perpendicular to the plane in which the pendulum moves, is called the axis of oscillation. There is also a certain point within every pendulum, into which, if all the matter that composes the pendulum were collected, or condensed as into a point, the times in which the vibrations would be performed, would not be altered by such condensation; and this point is called centre of oscillation. The length of the pendulum is usually estimated by the distance of this point below the centre of motion; being always near the bottom of the pendulum; but in a cylinder, or any other uniform prism or rod, it is at the distance of one third from the bottom, or two thirds from and below the centre of motion.

The length of a pendulum, so measured to its centre of oscillation, that it will perform each vibration in a second of time, thence called the second's pendulum, has, in the latitude of London been generally taken at $39\frac{2}{10}$ or $39\frac{1}{5}$ inches; but by some very ingenious and accurate experiments, the late celebrated Mr. George Graham found the true length to be $39\frac{128}{1000}$, inches, or $39\frac{1}{8}$ inches very nearly.

The length of the pendulum vibrating seconds at Paris, was found by Varin, Des Hays, De Glos, and Godin, to be $440\frac{5}{6}$ lines; by Picard $440\frac{1}{2}$ lines; and by Mairan $440\frac{17}{30}$ lines.

Galileo was the first who made use of a heavy body annexed to a thread, and suspended by it, for measuring time, in his experiments and observations. But according to Sturmius, it was Riccioli who first observed the isochronism of pendulums, and made use of them in measuring time. After him, Tycho, Langrene, Wendeline, Mersenne, Kircher, and others, observed the same thing; though it is said, without any intimation of what had been done by Riccioli. But it was the celebrated Huygens who first demonstrated the principles and properties of pendulums, and probably the first who applied them to clocks. He demonstrated, that if the centre of motion was perfectly fixed and immoveable, and all manner of friction, and resistance of the air, &c. removed, then a pendulum, once set in motion, would for ever continue to vibrate without any decrease of motion, and that all its vibrations would be perfectly isochronal, or performed in the same time. Hence the pendulum has universally been considered as the best chronometer or measurer of time. And as all pendulums of the same length perform their vibrations in the same time, without regard to their different weights, it has been suggested, by means of them, to establish an universal standard for all countries.

Pendulums are either simple or compound; and each of these may be considered either in theory, or as in practical mechanics among artisans.

A simple pendulum, in theory, consists of a single weight, as A, Plate Miscel. fig. 183. considered as a point, and an inflexible right line AC, supposed void of gravity or weight, and suspended from a fixed point or centre, C, about which it moves.

A compound pendulum, in theory, is a pendulum consisting of several weights moveable about one common centre of motion, but connected together so as to retain the same distance both from one another, and from the centre about which they vibrate.

The doctrine and laws of pendulums. 1. A pendulum raised to B, through the arc of the circle AB, will fall and rise again, through an equal arc, to a point equally high, as D; and thence will fall to A, and again rise to B; and thus continue rising and falling perpetually. For it is the same thing, whether the body falls down the inside of the curve BAD, by the force of gravity, or is retained in it by the action of the string; for they will both have the same effect; and it is otherwise known, from the oblique descents of bodies, that the body will descend and ascend along the curve in the manner above described.

Experience also confirms this theory, in any finite number of oscillations. But if they are supposed infinitely continued, a difference will arise. For the resistance of the air, and the friction and rigidity of the string about the centre C, will take off part of the force acquired in falling; whence it happens that it will not rise precisely to the same point from whence it fell.

Thus, the ascent continually diminishing the oscillation, this will be at last stopped, and the pendulum will hang at rest in its natural direction, which is perpendicular to the horizon.

Now, as to the real time of oscillation in a circular arc BAD; it is demonstrated by mathematicians, that if $p = 3.1416$, denote the circumference of a circle whose diameter is 1; $g = 16\frac{1}{12}$ feet, or 193 inches, the space a heavy body falls in the first second of time; and $r = CA$, the length of the pendulum, also $a = AE$, the height of the arch of vibration; then the time of each oscillation in the arc BAD, will be equal to $p\sqrt{\frac{r}{2g}} \times$ into the infinite series

$$1 + \frac{1^2a}{2^2d} + \frac{1^2 . 3^2a^2}{2^2 . 4^2d^2} + \frac{1^2 . 3^2 . 5^2a^3}{2^2 . 4^2 . 6^2d^3}$$ &c. where $d = 2r$ is the diameter of the arc described, or twice the length of the pendulum.

And here, when the arc is a small one, as in the case of the vibrating pendulum of a clock, all the terms of this series after the 2d may be omitted, on account of their smallness; and then the time of a whole vibration will be nearly equal to $p\sqrt{\frac{r}{2g}} \times (1 + \frac{a}{8r})$. So that the times of vibration of a pendulum in different small arcs of the same circle, are as $8r + a$; or 8 times the radius, added to the versed sine of the semi-arc.

And farther, if D denotes the number of degrees in the semi-arc AB, whose versed sine is a, then the quantity last mentioned, for the time of a whole vibration, is changed to $p\sqrt{\frac{r}{2g}} \times (1 + \frac{D^2}{52524})$. And therefore the times of vibration in different small arcs, are as $52524 + D^2$, or as the number 52524 added to the square of the number of degrees in the semi-arc AB.

2. Let CB be a semicycloid, having its base EC parallel to the horizon, and its vertex B downwards; and let CD be the other half of the cycloid, in a similar position to the former. Suppose a pendulum-string, of the same length with the curve of each semicycloid BC, or CD, having its end fixed in C, and the thread applied all the way close to the cycloidal curve BC, and consequently the body or pendulum-weight coinciding with the point B. If now the body is let go from B, it will descend by its own gravity, and in descending it will unwind the string from off the arch BC, as at the position CGH; and the ball G will describe a semicycloid BHA, equal and similar to BGC, when it has arrived at the lowest point A; after which, it will continue its motion, and ascend, by another equal and similar semicycloid AKD, to the same height D, as it fell from at B, the string now wrapping itself upon the other arch CID. From D it will descend again, and pass along the whole cycloid DAB, to the point B; and thus perform continual successive oscillations between B and D, in the curve of a cycloid; as it before oscillated in the curve of a circle, in the former case.

This contrivance to make the pendulum oscillate in the curve of a cycloid, is the invention of the celebrated Huygens, to make the pendulum perform all its vibrations in equal times, whether the arch, or extent of the vibration, is great or small; which is not the case in a circle, where the larger arcs take a longer time to run through them than the smaller ones do, as is well known both from theory and practice.

The chief properties of the cycloidal pendulum then, as demonstrated by Huygens, are the following: 1st. That the time of an oscillation in all arcs, whether larger or smaller, is always the same quantity, viz. whether the body begins to descend from the point B, and describes the semiarch BA; or that it begins at H, and describes the arch HA; or that it sets out from any other point; as it will still descend to the lowest point A in exactly the same time. And it is farther proved, that the time of a whole vibration through any double arc BAD, or HAK, &c. is in proportion to the time in which a heavy body will freely fall, by the force of gravity, through a space equal to $\frac{1}{2}$AC, half the length of the pendulum, as the circumference of a circle is to its diameter. So that, if $g = 16\frac{1}{12}$ feet denotes the space a heavy body falls in the first second of time, $p = 3.1416$ the circumference of a circle whose diameter is 1, and $r = AC$ the length of the pendulum; then, because, by the nature of descents by gravity, $\surd g : \surd \frac{1}{2}r :: 1'' : \surd \frac{r}{2g}$, that is, the time in which a body will fall through $\frac{1}{2}r$, or half the length of the pendulum; therefore, by the above proportion, as $1 : p :: \surd \frac{a}{2g} : p\surd \frac{r}{2g}$, which is the time of an entire oscillation in the cycloid.

And this conclusion is abundantly confirmed by experience. For example: if we consider the time of a vibration as 1 second, to find the length of the pendulum that will so oscillate in 1 second; this will give the equation $p\surd \frac{r}{2g} = 1$; which reduced, gives $r = \frac{2g}{p^2} = \frac{386}{3.1416^2}$ inches $= 39.11$, or $39\frac{1}{9}$ inches, for the length of the second's pendulum; which the best experiments shew to be about $39\frac{1}{8}$ inches.

3. Hence also, we have a method of determining, from the experiment the length of a pendulum, the space a heavy body will fall perpendicularly through in a given time; for, since $p\surd \frac{r}{2g} = 1$, therefore, by reduction, $g = \frac{1}{2}p^2 r$ is the space a body will fall through in the first second of time, when r denotes the length of the second's pendulum; and as constant experience shews that this length is nearly $39\frac{1}{8}$ inches, in the latitude of London, in this case g, or $\frac{1}{2}p^2 r$, becomes $\frac{1}{2} \times 3.1416^2 \times 39\frac{1}{8} = 193.07$ inches $= 16\frac{1}{12}$ feet, very nearly, for the space a body will fall in the first second of time, in the latitude of London: a fact which has been abundantly confirmed by experiments made there. And in the same manner, Mr. Huygens found the same space fallen through at Paris, to be 15 French feet.

The whole doctrine of pendulums oscillating between two semicycloids, both in theory and practice, was delivered by that author, in his Horologium Oscillatorium, sive Demonstrationes de Motu Pendulorum. And every thing that regards the motion of pendulums has since been demonstrated in different ways, and particularly by Newton, who has given an admirable theory on the subject, in his Principia, where he has extended to epicycloids the properties demonstrated by Huygens of the cycloids.

4. As the cycloid may be considered as coinciding in A, with any small arc of a circle described from the centre C, passing through A, where it is known the two curves have the same radius and curvature; therefore the time in the small arc of such a circle, will be nearly equal to the time in the cycloid; so that the times in very small circular arcs are equal, because these small arcs may be considered as portions of the cycloid, as well as of the circle. And this is one great reason why the pendulums of clocks are made to oscillate in as small arcs as possible, viz. that their oscillations may be the nearer to a constant equality.

This may also be deduced from a comparison of the times of vibration in the circle, and in the cycloid, as laid down in the foregoing articles. It has there been shewn, that the times of vibration in the circle and cycloid are thus, viz.

time in the circle nearly $p\surd \frac{r}{2g} \times (1 + \frac{a}{8r})$,

time in the cycloidal arc $p\surd \frac{r}{2g}$; where it is evident that the former always exceeds the latter in the ratio of $1 + \frac{a}{8r}$ to 1; but this ratio always approaches nearer to an equality, as the arc, or as its versed sine a, is smaller; till at length, when it is very small, the term $\frac{a}{8r}$ may be omitted, and then the times of vibration become both the same quantity, viz. $p\surd \frac{r}{2g}$.

Farther, by the same comparison, it appears, that the time lost in each second, or in each vibration of the seconds pendulum, by vibrating in a circle, instead of a cycloid, is $\frac{a}{8r}$, or $\frac{D^2}{52524}$; and consequently the time lost in a whole day of 24 hours, is $\frac{5}{3}D^2$ nearly. In like manner, the seconds lost per day by vibrating in the arc of Δ degrees, is $\frac{5}{3}\Delta^2$. Therefore, if the pendulum keeps true time in one of these arcs, the seconds lost or gained per day, by vibrating in the other, will be $\frac{5}{3}(D^2 - \Delta^2)$. So, for example, if a pendulum measures true time in an arc of 3 degrees, on each side of the lowest point, it will lose $11\frac{2}{3}$ seconds a day by vibrating 4 degrees; and $26\frac{2}{3}$ seconds a day by vibrating 5 degrees; and so on.

5. The action of gravity is less in those parts of the earth where the oscillations of the same pendulum are slower, and greater where these are swifter; for the time of oscillation is reciprocally proportional to $\surd g$. And it being found by experiment, that the oscillations of the same pendulum are slower near the equator, than in places farther from it; it follows that the force of gravity is less there; and consequently the parts about the equator are higher or farther from the centre, than the other parts; and the shape of the earth is not a true sphere, but somewhat like an oblate spheroid, flatted at the poles, and raised gradually towards the equator. And hence also the times of the vibration of the same pendulum, in different latitudes, afford a method of determining the true figure of the earth, and the proportion between its axis and the equatorial diameter.

Thus, M. Richer found by an experiment made in the island of Cayenne, about 4 degrees from the equator, that a pendulum 3 feet $8\frac{3}{5}$ lines long, which at Paris vibrated seconds, required to be shortened a line and a quarter to make it vibrate seconds. And many other observations have confirmed the same principle. See Newton's Principia, lib. iii. prop. 20. By comparing the different observations of the French astronomers, Newton apprehends that 2 lines may be considered as the length a second's pendulum ought to be decreased at the equator.

From some observations made by Mr. Campbell, in 1731, in Black-river, in Jamaica, 18° north latitude, it is collected, that if the length of a simple pendulum that swings seconds in London, is 39.126 English inches, the length of one at the equator would be 39.00, and at the poles 39.206.

And hence Mr. Emerson has computed the following Table, shewing the length of a pendulum that swings seconds at every 5th degree of latitude, as also the length of the degree of latitude there, in English miles.

Degrees of Latitude.	Length of Pendulum.	Length of the Degree.
	inches.	miles.
0	39.027	68.723
5	39 029	68.730
10	39.032	68.750
15	39.036	68.783
20	39.044	68.830
25	39.057	68.882
30	39.070	68.950
35	39.084	69.020
40	39.097	69.097
45	39.111	69.176
50	39.126	69.256
55	39.142	69.330
60	39.158	69 401
65	39.168	69 467
70	39.177	69.522
75	39.185	69.568
80	39.191	69.601
85	39.195	69.620
90	39.197	69.628

6. If two pendulums vibrate in similar arcs, the times of vibration are in the sub-duplicate ratio of their lengths. And the lengths of pendulums vibrating in similar arcs, are in the duplicate ratio of the times of a vibration directly; or in the reciprocal duplicate ratio of the number of oscillations made in any one and the same time. For, the time of vibration t being as $p\surd \frac{r}{2g}$, where p and g are constant or given, therefore t is as $\surd r$, and r as t^2. Hence therefore the length of a half-second pendulum will be $\frac{1}{4}r$, or $\frac{39\frac{1}{8}}{4} = 9.781$ inches; and the length of the quarter-second pendulum will be $\frac{1}{16}r = \frac{39\frac{1}{8}}{16} = 2.445$ inches; and so of others.

7. The foregoing laws, &c. of the motion of pendulums, cannot strictly hold good, unless the thread that sustains the ball is void of weight, and the gravity of the whole ball is collected into a point. In practice, therefore, a very fine thread, and a small ball, but of a very heavy matter, are to be used. But a thick thread, and a bulky ball, disturb the motion very much; for in that case, the simple pendulum becomes a compound one; it being much the same thing, as if several weights were applied to the same inflexible rod in several places.

8. Mr. Krafft, in the new Petersburgh Memoirs, vols. 6 and 7, has given the result of many experiments upon pendulums, made in different parts of Russia, with deductions from them, from whence he derives this theorem: if x is the length of a pendulum that swings seconds in any given latitude l, and in a temperature of 10 degrees of Reaumur's thermometer, then will the length of that pendulum, for that latitude, be thus expressed, viz.

$x = (439{\cdot}178 + 2{\cdot}321 + \sin.^2 l)$ lines of a French foot. And this expression agrees very nearly, not only with all the experiments made on the pendulum in Russia, but also with those of Mr. Graham, and those of Mr. Lyons in 79° 50′ north latitude, where he found its length to be 441·38 lines.

Pendulum, *simple*, in mechanics, an expression commonly used among artists, to distinguish such pendulums as have no provision for correcting the effects of heat and cold, from those that have such provision. Also simple pendulum, and detached pendulum, are terms sometimes used to denote such pendulums as are not connected with any clock, or clockwork.

Pendulum, *compound*, in mechanics, is a pendulum whose rod is composed of two or more wires or bars of metal. These, by undergoing different degrees of expansion and contraction, when exposed to the same heat or cold, have the difference of expansion or contraction made to act in such a manner as to preserve constantly the same distance between the point of suspension and centre of oscillation, although exposed to very different and various degrees of heat or cold. There are a great variety of constructions for this purpose; but they may be all reduced to the gridiron, the mercurial, and the lever pendulum.

It may be just observed by the way, that the vulgar method of remedying the inconvenience arising from the extension and contraction of the rods of common pendulums, is by supplying the bob, or small ball, with a screw at the lower end; by which means the pendulum is at any time made longer or shorter, as the ball is screwed downwards or upwards, and thus the time of its vibration is kept continually the same.

The gridiron pendulum was the invention of Mr. John Harrison, a very ingenious artist, and celebrated for his invention of the watch for finding the difference of longitude at sea, about the year 1725, and of several other timekeepers and watches since that time; for all which he received the parliamentary reward of between 20,000 and 30,000 pounds. It consists of five rods of steel, and four of brass, placed in an alternate order, the middle rod being of steel, by which the pendulum-ball is suspended; these rods of brass and steel, thus placed in an alternate order, are so connected with each other at their ends, that while the expansion of the steel rods has a tendency to lengthen the pendulum, the expansion of the brass rods, acting upwards, tends to shorten it. And thus, when the length of the brass and steel rods is duly proportioned, their expansions and contractions will exactly balance and correct each other, and so preserve the pendulum invariably of the same length. The simplicity of this ingenious contrivance is much in its favour; and the difficulty of adjustment seems the only objection to it. See Longitude.

Mr. Harrison, in his first machine for measuring time at sea, applied this combination of wires of brass and steel, to prevent any alterations by heat or cold; and in the machines or clocks he has made for this purpose, a like method of guarding against the irregularities arising from this cause is used.

The mercurial pendulum was the invention of the ingenious Mr. Graham, in consequence of several experiments relating to the materials of which pendulums might be formed, in 1715. Its rod is made of brass, and branched towards its lower end, so as to embrace a cylindric glass vessel 13 or 14 inches long, and about two inches diameter; which being filled about twelve inches deep with mercury, forms the weight or ball of the pendulum. If upon trial the expansion of the rod is found too great for that of the mercury, more mercury must be poured into the vessel; if the expansion of the mercury exceeds that of the rod, so as to occasion the clock to go fast with heat, some mercury must be taken out of the vessel, so as to shorten the column. And thus may the expansion and contraction of the quicksilver in the glass be made exactly to balance the expansion and contraction of the pendulum-rod, so as to preserve the distance of the centre of oscillation from the point of suspension invariably the same.

Mr. Graham made a clock of this sort, and compared it with one of the best of the common sort, for three years together; when he found the errors of his own but about one-eighth part of those of the latter.

Mr. John Ellicott also, in the year 1738, constructed a pendulum on the same principle, but differing from Mr. Graham's in many particulars. The rod of Mr. Ellicott's pendulum was composed of two bars only; the one of brass, and the other of steel. It had two levers, each sustaining its half of the ball or weight; with a spring under the lower part of the ball to relieve the levers from a considerable part of its weight, and so to render their motion more smooth and easy. The one lever in Mr. Graham's construction was above the ball; whereas both the levers in Mr. Ellicott's were within the ball, and each lever had an adjusting screw, to lengthen or shorten the lever, so as to render the adjustment the more perfect.

Notwithstanding the great ingenuity displayed by these very eminent artists on this construction, it must farther be observed, in the history of improvements of this nature, that Mr. Cumming, another eminent artist, has given, in his Essays on the Principles of Clock and Watch Work, an ample description, with plates, of a construction of a pendulum with levers, in which it seems he has united the properties of Mr. Graham's and Mr. Ellicott's, without being liable to any of the defects of either. The rod of this pendulum is composed of one flat bar of brass, and two of steel; he uses three levers within the ball of the pendulum; and, among many other ingenious contrivances for the more accurate adjusting of this pendulum to mean time, it is provided with a small ball and screw below the principal ball or weight, one entire revolution of which on its screw will only alter the rate of the clock's going one second per day; and its circumference is divided into 30, one of which divisions will therefore alter its rate of going one second in a month.

Pendulum-clock, is a clock having its motion regulated by the vibration of a pendulum.

It is controverted between Galileo and Huygens, which of the two first applied the pendulum to a clock.

After Huygens had discovered, that the vibration made in arcs of a cycloid, however unequal they might be in extent, were all equal in time; he soon perceived, that a pendulum applied to a clock, so as to make it describe arcs of a cycloid, would rectify the otherwise unavoidable irregularities of the motion of the clock; since, though the several causes of those irregularities should occasion the pendulum to make greater or smaller vibrations, yet, by virtue of the cycloid, it would still make them perfectly equal in point of time; and the motion of the clock governed by it, would therefore be preserved perfectly equable. But the difficulty was, how to make the pendulum describe arcs of a cycloid; for naturally the pendulum, being tied to a fixed point, can only describe circular arcs about it.

Here Mr. Huygens contrived to fix the iron rod or wire, which bears the ball or weight at the top, to a silken thread, placed between two cycloidal cheeks, or two little arcs of a cycloid, made of metal. Hence the motion of vibration, applying successively from one of those arcs to the other, the thread, which is extremely flexible, easily assumes the figure of them, and by that means causes the ball or weight at the bottom to describe a just cycloidal arc.

This is doubtless one of the most ingenious and useful inventions many ages have produced; by means of which it has been asserted there have been clocks that would not vary a single second in several days; and the same invention also gave rise to the whole doctrine of involute and evolute curves, with the radius and degree of curvature, &c.

It is true, the pendulum is still liable to its irregularities, how minute soever they may be. The silken thread by which it was suspended, shortens in moist weather, and lengthens in dry; by which means the length of the whole pendulum, and consequently the times of the vibrations, are somewhat varied.

To obviate this inconvenience, M. De la Hire, instead of a silken thread, used a little fine spring; which was not indeed subject to shorten and lengthen, from those causes; yet he found it grew stiffer in cold weather, and then made its vibrations faster than in warm: to which also we may add its expansion and contraction by heat and cold. He therefore had recourse to a stiff wire or rod, firm from one end to the other. Indeed, by this means he renounced the advantages of the cycloid; but he found, as he says, by experience, that the vibrations in circular arcs are performed in times as equal, provided they are not of too great extent, as those in cycloids. But the experiments of sir Jonas Moore, and others, have demonstrated the contrary.

The ordinary causes of the irregularities of pendulums Dr. Derham ascribes to the alterations in the gravity and temperature of the air, which increase and diminish the weight of the ball, and by that means make the vibrations greater and less; an accession of weight in the ball being found by experiment to accelerate the motion of the pendulum; for a weight of six pounds added to the ball, Dr. Derham found made his clock gain thirteen seconds every day.

A general remedy against the inconveniences of pendulums, is to make them long, the ball heavy, and to vibrate but in small arcs. These are the usual means employed in England; the cycloidal cheeks being generally neglected.

Pendulum-clocks resting against the same rail have been found to influence each other's motion. See the Philos. Trans. numb. 453, sects. 5 and 6, where Mr. Ellicott has given a curious and exact account of this phenomenon.

Pendulum, *royal*, a name used among us for a clock, whose pendulum swings seconds, and goes eight days without winding up; shewing the hour, minute, and second. The numbers in such a piece are thus calculated: First cast up the seconds in twelve hours, which are the beats in one turn of the great wheel; and they will be found to be $43200 = 12 \times 60 \times 60$. The swing-wheel must be 30, to swing 60 seconds in one of its revolutions; now let the half of 43200, viz. 21600, be divided by 30, and the quotient will be 720, which must be separated into quotients. The first of these must be 12, for the great wheel, which moves round once in 12 hours. Now 720 divided by 12, gives 60; which may also be conveniently broken into two quotients, as 10 and 6, or 12 and 5, or 8 and $7\frac{1}{2}$, which last is most convenient; and if the pinions are all taken 8, the work will stand thus:

$$\begin{array}{l} 8\ )\ 96\ (\ 12 \\ 8\ )\ 64\ (\ \ 8 \\ 8\ )\ 60\ (\ 7\tfrac{1}{2} \\ \hline \qquad\quad 30 \end{array}$$

According to this computation, the great wheel will go round once in 12 hours, to shew the hour; the next wheel once in an hour, to shew the minutes; and the swing-wheel once in a minute, to shew the seconds. See CLOCKWORK.

PENEA, in botany, a genus of the monogynia order, in the tetrandria class of plants; and in the natural method ranking with those of which the order is doubtful. The calyx is diphyllous; the corolla campanulated; the style quadrangular; the capsule tetragonal, quadrilocular, and octospermous.

PENELOPE, a genus of birds of the order of gallinæ. The characters of which are: the beak is bare at the base; the head is covered with feathers; the neck is quite bare; the tail consists of twelve principal feathers; and the feet are for the most part bare. Linnæus, in the Systema Naturæ, enumerates six species: 1. Penelope meleagris satyra, or horned pheasant. Latham calls it the horned turkey. This species is larger than a fowl, and smaller than a turkey. The colour of the bill is brown; the nostrils, forehead, and space round the eyes are covered with slender black hairy feathers; the top of the head is red. Behind each eye there is a fleshy callous blue substance like a horn, which tends backward. On the forepart of the neck and throat there is a loose flap, of a fine blue colour, marked with orange spots, the lower part of which is beset with a few hairs; down the middle it is somewhat looser than on the sides, being wrinkled. The breast and upper part of the back are of a full red colour. The neck and breast are inclined to yellow; the other parts of the plumage and tail are of a rufous brown, marked all over with white spots encompassed with black. The legs are somewhat white, and furnished with a spur behind each. It is a native of Bengal.

2. The penelope meleagris cristata, is about the size of a fowl, being about two feet six inches long. The bill is two inches long, and of a black colour; the sides of the head are covered with a naked purplish blue skin, in which the eyes are placed: beneath the throat for an inch and a half, the skin is loose, of a fine red colour, and covered only with a few hairs. The top of the head is furnished with long feathers, which the bird can erect as a crest at pleasure; the general colour of the plumage is brownish black, glossed over with copper in some lights; but the wing-coverts have a greenish and violet gloss. They inhabit Brasil and Guiana, where they are often made tame. They frequently make a noise not unlike the word jacu. Their flesh is much esteemed.

3. Penelope crax cumanensis, called by Latham, &c. yacou. It is bigger than a common fowl. The bill is black; the head feathers are long, pointed, and form a crest, which can be erected at pleasure. It has a naked membrane, or kind of wattle, of a dull black colour. The blue skin comes forward on the bill, but is not liable to change colour like that of the turkey. The plumage has not much variation; it is chiefly brown, with some white markings on the neck, breast, wing-coverts, and belly. This species inhabits Cayenne, but is a very rare bird, being met with only in the inner parts, or about the Amazons' country. Those seen at Cayenne are mostly tame ones, for it is a familiar bird, and will breed in that state, and mix with other poultry. It makes the nest on the ground, and hatches the young there, but is at other times mostly seen on trees. It frequently erects the crest, when pleased, or taken notice of, and likewise spreads the tail upright like a fan, in the manner of the turkey.

4. The pipile, or as it is called, crax pipile, is black in the belly, and the back brown stained with black. The flesh on the neck is of a green colour. It is about the bigness of the former, and has a hissing noise. The head is partly black and partly white, and is adorned with a short crest. The space about the eyes, which are black, is white; the feet are red. It inhabits Guiana.

5. The marail is about the size of a fowl, and shaped somewhat like it. The space round the eyes is bare, and of a pale red; the chin, throat, and forepart of the neck, are scarcely covered with feathers; but the throat itself is bare, and the membrane elongated to half an inch or more; both this and the skin round the eyes change colour, and become deeper and thicker, when the bird is irritated. The head feathers are longish, so as to appear like a crest when raised up, which the bird often does when agitated; at which time it also erects those of the whole body, and so disfigures itself as to be scarcely known: the general colour of the plumage is a greenish black. This species is common in the woods of Guiana, at a distance from the sea. The female makes her nest on some low bushy tree, as near the trunk as possible, and lays three or four eggs. When the young are hatched, they descend with the mother after ten or twelve days. The mother acts as other fowls, scratching on the ground like a hen, and brooding the young, which quit their nurse the moment they can shift for themselves. They have two broods in a year; one in December or January, the other in May or June. The best time of finding these birds is morning or evening, being then met with on such trees whose fruit they feed on, and are discovered by some of it falling to the ground. The young birds are easily tamed, and seldom forsake the places where they have been brought up; they need not be housed as they prefer the roosting on tall trees to any other place. Their flesh is much esteemed.

6. The vociferating penelope. The bill of this bird is of a greenish colour: the back is brown, the breast green, and the belly of a whitish brown. Latham calls it the crying curassow. It is about the bigness of a crow.

PENGUIN, in ornithology. See ALCA.

PENNANTIC, a genus of the polygamia diœcia class and order. There is no calyx; the corolla is five-petalled; stamina five: perianthum three-sided, two-celled. There is one species, a herb of New Zealand.

PENNATULA, or SEA-PEN, a genus of zoophyte, which,* though it swims about freely in the sea, approaches near to the gorgonia. This genus has a bone along the middle of the inside, which is its chief support; and this bone receives the supply of its osseous matter by the same polype-mouths that furnish it with nourishment. Linnæus reckons seven species. It is certainly an animal, and as such is free or locomotive. Its body generally expands into processes on the upper parts, and these processes or branches are furnished with rows of tubular denticles; they have a polype-head proceeding from each tube.

The sea-pen is not a coralline, but distinguished from it by this specific difference; corals, corallines, alcyonia, and all that order of beings, adhere firmly by their bases to submarine substances, but the sea-pen either swims about in the water or floats upon the surface.

Its general appearance greatly resembles that of a quill-feather of a bird's wing; it is about four inches long, and of a reddish colour; along the back there is a groove from the quill part to the extremity of the feathered part, as there is in a pen; the feathered part consists of fins proceeding from the stem. The fins move the animal backward and forward in the water, and are furnished with suckers or mouths armed with filaments.

Dr. Boadsch of Prague had an opportunity of observing one of these animals alive in the water, and he gives the following account of what he saw: "A portion of the stem contracted, and became of a strong purple colour, so as to have the appearance of a ligature round it; this apparent ligature, or zone, moved upwards and downwards successively through the whole length of the stem, as well the feathered as the naked part; it began at the bottom, and moving upwards to the other extremity, it there disappeared, and at the same instant appeared again at the bottom, and ascended as before; but as it ascended through the feathered or pinnated part, it became paler." When this zone is much constricted, the trunk above it swells, and acquires the form of an onion; the constriction of the trunk gives the colour to the zone, for the intermediate parts are paler in proportion as the zone becomes deeper. The end of the naked trunk is sometimes curved like a hook; and at its extremity there is a sinus or chink, which grows deeper while the purple ring is ascending, and shallower as it is coming down. The fins have four motions, upward and downward, and backward and forward, from right to left, and from left to right. The fleshy filaments, or claws, move in all directions; and with the cylindrical part from which they proceed are sometimes protruded from the fins, and sometimes hidden with them.

Upon dissecting this animal the following phenomena were discovered: When the trunk was opened lengthwise, a saltish liquor flowed out of it, so viscid as to hang down an inch. The whole trunk of the stem was found to be hollow, the outward membrane being very strong, and about the tenth part of an inch thick; within this membrane appeared another much thinner; and between these two membranes, in the pinnated part of the trunk, innumerable little yellowish eggs, about the size of a white poppy-seed, were seen floating in a whitish liquor; about three parts of the cavity within the inner membrane is filled by a kind of yellowish bone; this bone is about two inches and a half long, and one twentieth of an inch thick; in the middle it is square, but towards the ends it grows round and very taper, that end being finest which is next the pinnated part of the trunk. This bone is covered in its whole length with a clear yellowish skin, which at each end runs out into a ligament; one is inserted in the top of the pinnated trunk, and the other in the top of the naked trunk; by the help of the upper ligament the end of the bone is either bent into an arch, or disposed in a straight line. The fins are composed of two skins; the outward one is strong and leathery, and covered over with an infinite number of crimson streaks; the inner skin is thin and transparent; the suckers are also in the same manner composed of two skins, but the outward skin is something softer. Both the fins and suckers are hollow, so that the cavity of the suckers may communicate with those of the fins, as the cavity of the fins does with that of the trunk. Dr. Shaw, in the History of Algiers, says, that these animals are so luminous in the water, that in the night the fishermen discover fishes swimming about in various depths of the sea by the light they give. From this extraordinary quality, Linnæus calls this species of the sea-pen pennatula phosphorea; and remarks, after giving the synonyms of other authors, habitat in oceano fundum illuminans.

There are other kinds of sea-pens, or species of this animal, which have not a resemblance to a pen.

PENNY, formerly a silver, but now a copper coin.

The penny was the first silver coin struck in England by our Saxon ancestors, being the 240th part of their pound, and its true weight was about $22\frac{1}{2}$ grains troy.

In Etheldred's time, the penny was the 20th part of the troy ounce, and equal in weight to our threepence; which value it retained till the time of Edward the Third.

Till the time of king Edward the First, the penny was struck with a cross so deeply sunk in it, that it might, on occasion, be easily broken, and parted into two halves, thence called halfpence; or into four, thence called fourthings, or farthings. But that prince coined it without the cross; instead of which he struck round halfpence and farthings: though there are said to be instances of such round halfpence having been made in the reign of Henry the First, if not also in those of the two Williams.

Edward the First also reduced the weight of the penny to a standard; ordering that it should weigh 32 grains of wheat, taken out of the middle of the ear. This penny was called the penny sterling; and 20 of them were to weigh an ounce, whence the penny became a weight as well as a coin.

By the 9th of Edward the Third, it was diminished to the 26th part of the troy ounce; by the 2d of Henry the Sixth it was the 32nd part; by the 5th of Edward the Fourth, it became the 40th, and also by the 36th of Henry the Eighth, and afterwards the 45th; but by the 2nd of Elizabeth, 60 pence were coined out of the ounce, and during her reign 62, which last proportion is still observed in our times.

Penny-weight, a troy weight, being the 20th part of an ounce, containing 24 grains; each grain weighing a grain of wheat gathered out of the middle of the ear, well dried. The name took its rise from its being actually the weight of one of our ancient silver pennies. See Penny.

PENTAGON, in geometry, a figure of five sides and five angles.

If the five sides are equal, the angles are so too, and the figure is called a regular pentagon; such is ABCDE (Plate Miscel. fig. 184), inscribed in the circle.

The most considerable property of a pentagon is, that one of its sides DE, is equal in power to the sides of a hexagon and a decagon, inscribed in the same circle ABCDE; that is, the square of the side DE, is equal to the sum of the squares of the sides dE and Eb.

The area of a pentagon, like that of any other polygon, may be obtained by resolving it into triangles. See the articles Triangle and Polygon.

Pappus has also demonstrated, that twelve regular pentagons contain more than twenty triangles inscribed in the same circle.

The dodecahedron, which is the fourth regular solid, consists of twelve pentagons.

In fortification, pentagon denotes a fort with five bastions.

PENTAGRAPH, or Parallelogram, an instrument whereby designs of any kind may be copied in what proportion you please, without being skilled in drawing.

A pentagraph is composed of 4 bars, ABDE, Plate Pedometer, &c. fig. 4, usually of brass; the bar A is jointed to B at b about the middle, and at a it is connected with E: the bar B is the same length as A; and at d is jointed to the bar D, whose end is connected with the end of E; these four bars form a parallelogram: thus, ba = D, and bd = E. To the other end of the bar A, a tube F is soldered, through which a pointed brass rod e, called the tracer, is put; the end of the bar B has a slider G upon it, which has a tube similar to F; another slider I of the same kind is mounted on the bar D. These sliders have screws, by which they can be fixed at any distance. Under each of the joints of the base, a small tube is fixed, in the bottom of which is a small castor as H, which makes the instrument run easily on the table. When the instrument is used, the two sliders GI must be set exactly in a line with the tube F; when it is required to make a copy of a drawing of the same size, the sliders must be set so that from F to I is the same distance as from I to G; the tube I must then have a wire put through it, whose lowest end is fast screwed to a heavy leaden weight, L; this must have three sharp points in the under side, so that when it is set on the table it may not be liable to move; then if a design or drawing is laid under the tube F, and the point of the tracer drawn over the lines of it, the point of the pencil at G will describe a similar figure. If the drawing is to be reduced to one-half of the size, the weight must be put to the slider G, and the pencil into I, without moving either slider; then the distance from the tracer to the fixed point or weight L, is twice the distance of the pencil to the weight. The rule for setting the sliders for any proportion is, as the distance between the tracer e and the fixed point L, is to the distance between the pencil G and the same, so is the length of any line described by the tracer, to the length of the line at the same time described by the pencil. To avoid the trouble of measuring these distances each time, the bars B and D are divided into ten or twenty of the most common proportions, by which divisions the sliders are to be fixed.

The construction of one of the sliders is shewn in fig. 5: where M is a piece of brass, to one corner of which a tube g is soldered; an opening of the same width as the bar is cut in this, and a cover N is screwed on with two screws: this cover has a screw with a mill-head through it, by which the slider is fixed. A piece of brass O, a little bent, is put between the bar and the under side of the cover, and whose elasticity prevents the slider moving too freely when the screw is slack, and defends the bar from being scratched by the ends of the screw when it is fixed.

Fig. 6, describes the method of making the joints of the rods: P is the end of one bar, which has a steel spindle p screwed fast to it; the other bar o has a cock v, screwed on, whose upper end projects over the tube t, and has a hole through it, just over the hole in the tube. The ends of the spindle P are put between the holes in the cock and the hole in the tube; if the spindles are well fitted, this joint is very steady, and without any shake. The lower end of the tube t has a hole drilled in it, into which the spindle W of the castor is put; the castor is kept from falling out of the tube, by the point of a small screw going through the side of the tube t, which takes into a notch cut round in the top of the spindle w. When the machine is used, a fine line, RR, is put through rings in the cocks bd, and tied to the pencil; the other end has a loop to be hooked over the thumb of the operator, by pulling which he can raise the pencil at D, when he does not wish it to mark.

PENTAMETER, in antient poetry, a kind of verse consisting of five feet, or metres, whence the name.

PENTANDRIA, in botany, one of Linnæus's class of plants, the fifth in order; the characters of which are, that all the plants comprehended in it have hermaphrodite flowers, with five stamina or male parts in each; they are subdivided into orders, which are denominated monogynia, digynia, trigynia, &c. according as there are one, two, three, &c. pistils, or female parts, in each flower.

PENTAPETES, a genus of the dodecandria order, in the monadelphia class of plants, and in the natural method ranking under the 37th order, columniferæ. The calyx is double; the stamina are 15 in number, of which five are castrated and long; the capsule quinquelocular and polyspermous. There is but one species known in the gardens of this country, viz. the phœnicia, with halbert-pointed, spear-shaped, sawed leaves. It is an annual plant, a native of India.

PENTHORUM, a genus of the pentagynia order, in the pentandria class of plants. The calyx is quinquefid; there are either five petals or none; the capsule is five-pointed and quinquelocular. There is one species.

PENTSLEMON, a genus of the didynamia angiospermia class and order. The calyx is five-leaved; the corolla bilabiate, ventricose; rudiment of a 5th stamen, bearded above; capsules two-celled. There are 2 species.

PENUMBRA, in astronomy, a partial shade observed between the perfect shadow and the full light in an eclipse.

It arises from the magnitude of the sun's body; for were he only a luminous point, the shadow would be all perfect; but by reason of the diameter of the sun, it happens that a place which is not illuminated by the whole body of the sun, does yet receive rays from a part thereof. See ECLIPSE.

PEPLIS, a genus of the monogynia order, in the hexandria class of plants, and in the natural method ranking under the 17th order, calycanthemæ. The perianthium is campanulated; the mouth cleft in 12 parts; there are six petals inserted into the calyx; the capsule is bilocular. There are 2 species, creeping plants.

PEPPER. See PIPER.

PERAMBULATOR, in surveying, an instrument for measuring distances, called also pedometer, way-wiser, and surveying wheel.

Plate Perambulator, &c. figs. 1, 2, and 3, represent a perambulator; AA, fig. 1, is a wheel of mahogany, tired with iron, and made very strong; its circumference must be exactly ninety-nine inches, or half a pole. This is placed so as to turn round in an opening cut in the piece BD, which forms the frame. In the arm B, a groove is cut from the centre of the wheel to the dial *b*; the end of the spindle comes through the wood into this groove, and has a small crown-wheel of eight teeth upon it. This works another wheel of eight teeth fixed on a long spindle, which conveys motion from the wheel beneath to the dial *b*. The groove containing this spindle has a slip of wood screwed over it, to keep out dirt, &c.; and the end of this spindle has a square hole in it, into which is put the square end of the spindle *a* (fig. 2). This has an endless screw *d* upon it, which works a worm-wheel *e* of twenty-four teeth, having a pinion of twelve beneath it: and below this has a wheel *f* of thirty-six. The pinion works the wheel *g* of forty; and the wheel *f* turns the pinion *h* of twelve, whose spindle carries the short hand of the dial (fig. 3). The arbour of the wheel *g* comes up through the dial, and has the hand F fig. 3 on it; as also a pinion of eight, which turns *g* of sixty-four. In the arbor of the wheel *h*, is a pinion *i* of six, taking into *k* of seventy-two; this is here supposed to be half broken away, to shew the wheels beneath. The spindle of this is hollow, and is put over the arbor of the wheel *g*; and carries the hand G fig. 3. HHHH are four pillars, by which the two plates forming the frame for the wheels are held together. The wheel *g* (fig. 2) is not fixed fast to its spindle, but is held between a brass plate *l* and another beneath; the friction of these causes the wheel to turn the hand, and at the same time leaves the hand at liberty to be set without moving the wheels. The plate *l* has a pin *n* fixed in it; which pin takes against a projecting part of the handle of the hammer *m*, so as to lift it up when the plate is turned, and let the spring *p* through *w* against the bell K.

When any distance is to be measured by this machine, the operator takes hold of the handle, and wheels it along in as straight a line as he can. The circumference of the wheel being ninety-nine inches (or half a pole), and the two wheels in the piece being equal, the screw *d* (fig. 2) will turn once in each turn of the great wheel, or twice for every pole the machine is wheeled. This screw must be so cut that the great wheel must turn twenty-four times for one turn of the wheel *e*, and also the wheel *f* on the same spindle as this must turn a pinion *h* of one-third of its number of teeth. The short hand on the dial which it carries will for every revolution require eight turns of the great wheel, = four poles, = one chain. The circle is divided into 100 parts, each = one link. The pinion of twelve on the arbor of the wheel *e*, turning once for twenty-four turns of the great wheel, makes the wheel *g* require for each revolution eighty turns of the great wheel, or for the machine to be wheeled ten chains (or turns of the short hand) = 40 poles (as the circle of its hand is divided), = one furlong: and at each revolution of this wheel, the hammer *m* will strike the bell K. The pinion of eight on the arbor of the wheel *g*, works *h* of sixty-four; and its pinion *i* turns K of seventy-two; the result of which will be, that the hand on the spindle of *k* will require for each revolution 7680 turns of the great wheel, or for the machine to be wheeled 3840 poles, = 960 chains or turns of the short hand, = 96 furlongs or turns of the hand F and strokes on the bell, = twelve miles as the dial is divided.

The use of this instrument is obvious from its construction. Its proper office is in the surveying of roads and large distances, where a great deal of expedition, and not much accuracy, is required. It is evident, that driving it along, and observing the hands, has the same effect as dragging the chain, and taking account of the chains and links.

Its advantages are, its handiness and expedition; its contrivance is such, that it may be fitted to the wheel of a coach, in which state it performs its office, and measures the road without any trouble.

PERCA, PERCH, a genus of fishes of the order thoracici; the generic character is, teeth sharp, incurvate; gill-covers triphyllous, scaly, serrated; dorsal fin spiny on the fore part; scales (in most species) hard and rough.

1. Perca fluviatilis, common perch. The perch is an inhabitant of clear rivers and lakes throughout almost all parts of Europe, arriving sometimes to a very large size, and to the weight of eight, nine, or ten pounds; its general size, however, is far smaller, usually measuring from six to fifteen inches in length, and weighing from two ounces to four pounds. The colour of the perch is brownish-olive, sometimes accompanied by a slight gilded tinge on the sides, and commonly marked by five or six moderately broad, blackish, transverse, semidecurrent bars; the dorsal fin is of a pale violet-brown, marked at the back of the spiny part by a roundish black spot accompanied by a smaller one; the rest of the fins, with the tail, are red.

The perch usually spawns in the early part of the spring, depositing a kind of extended bands of gluten, throughout which are disposed the ova in a sort of reticular direction. It is of a gregarious disposition, and is fond of frequenting deep holes in rivers which flow with a gentle current; it is extremely voracious, and bites eagerly at a bait; it is tenacious of life, and may be carried to the distance of sixty miles in dry straw, and yet survive the journey. It is one of those fishes which were held in repute at the tables of the antient Romans, and is in general esteem at the present day, being considered as firm and delicate. In some of the northern regions a species of isinglass is prepared from the skin.

2. Perca lucioperca, sandre perch. General length from one to two feet, but said sometimes to arrive at four feet; shape longer than in the preceding species, having something of the habit of a pike, the head being rather produced, and the mouth furnished with large teeth: general colour silvery grey, deepest on the back, and with a pretty strong tinge of blue on the head and gill-covers; sides of the back marked by pretty numerous, slightly decurrent, blackish bands; dorsal fins, by numerous dusky spots; pectoral fins, reddish; the rest dusky. Native of clear rivers and lakes in the middle parts of Europe, and highly esteemed for the table: in general manners said to resemble the common perch, but to be far less tenacious of life.

3. Perca cernua, ruffe perch. Length about six inches; shape more slender than that of the common perch; head rather large, and somewhat flattened; teeth small; colour subolivaceous, with numerous dusky spots disposed over the body, dorsal, pectoral fins, and tail; abdomen whitish; native of many parts of Europe; chiefly frequenting clear rivers, assembling in large shoals, and keeping in the deepest part of the water. There are about forty species of this genus. See Plate Nat. Hist. figs. 323, 324.

PERCH, in land-measuring, a rod or pole of $16\frac{1}{2}$ feet in length, of which 40 in length and 4 in breadth make an acre of ground. But, by the customs of several counties, there is a difference in this measure. In Staffordshire it is 24 feet; and in the forest of Sherwood 25 feet, the foot being there 18 inches long; and in Herefordshire a perch of ditching is 21 feet, the perch of walling $16\frac{1}{2}$ feet, and a pole of denshiered ground is 12 feet, &c.

PERCUSSION, in mechanics, the impression a body makes in falling or striking upon another, or the shock of two bodies in motion.

Percussion is either direct or oblique; direct, when the impulse is given in a line perpendicular to the point of contact; and oblique, when it is given in a line oblique to the point of contact.

The ratio which an oblique stroke bears to a perpendicular one, is as the sine of the angle of incidence to the radius. Thus, let *ab* (Plate Miscel. fig. 185) be the side of any body on which an oblique force falls, with the direction *da*; draw *dc* at right angles to *db*, a perpendicular let fall from *d* to the body to be moved, and make *ad* the radius of a circle; it is plain that the oblique force *da*, by the laws of composition and resolution of motions, will be resolved into the two forces *dc* and *bd*; of which *dc*, being parallel to *ab*, has no energy or force to move that body; and consequently, *db* expresses all the power of the stroke or impulse on the body to be moved. But *db* is the right sine of the angle of incidence *dab*; wherefore the oblique force *da*, to one falling perpendicularly, is as the sine of the angle of incidence to the radius.

Percussion, *centre of*, is that part or point of a pendulous body, which will make the greatest impression on an obstacle that is opposed to it whilst vibrating; for if the obstacle is opposed to it at different distances from the point of suspension, the stroke or percussion will not be equally powerful, and it will soon appear that this centre of percussion does not coincide with the centre of gravity.

The force of percussion is the same as the momentum, or quantity of motion, and is represented by the product arising from the mass or quantity of matter moved, multiplied by the velocity of its motion; and that without any regard to the time or duration of action; for its action is considered totally independant of time, or but as for an instant, or an infinitely small time.

This consideration will enable us to resolve a question that has been greatly canvassed among philosophers and mathematicians, viz. what is the relation between the force of percussion and mere pressure or weight? For we hence infer, that the former force is infinitely, or incomparably, greater than the latter. For, let M denote any mass, body, or weight, having no motion or velocity, but simply its pressure; then will that pressure or force be denoted by M itself, if it is considered as acting for some certain finite assignable time; but, considered as a force of percussion, that is, as acting but for an infinitely small time, its velocity being 0, or nothing, its percussive force will be $0 \times M$, that is 0, or nothing; and is therefore less than any the smallest percussive force whatever. Again, let us consider the two forces, viz. of percussion and pressure, with respect to the effects they produce. Now the intensity of any force is very well measured and estimated by the effect it produces in a given time: but the effect of the pressure M, in 0 time, or an infinitely small time, is nothing at all; that is, it will not, in an infinitely small time, produce, for example, any motion, either in itself, or in any other body; its intensity, therefore, as its effect, is infinitely less than any the smallest force of percussion. It is true, indeed, that we see motion and other considerable effects produced by mere pressure, and to counteract which it will require the opposition of some considerable percussive force; but then it must be observed, that the former has been an infinitely longer time than the latter in producing its effect; and it is no wonder in mathematics that an infinite number of infinitely small quantities makes up a finite one. It has therefore only been for want of considering the circumstance of time, that any question could have arisen on this head. Hence the two forces are related to each other, only as a surface is to a solid or body; by the motion of the surface through an infinite number of points, or through a finite right line, a solid or body is generated; and by the action of the pressure for an infinite number of moments, or for some finite time, a quantity equal to a given percussive force is generated; but the surface itself is infinitely less than any solid, and the pressure infinitely less than any percussive force. This point may be easily illustrated by some familiar instances, which prove at least the enormous disproportion between the two forces, if not also their absolute incomparability. And first, the blow of a small hammer, upon the head of a nail, will drive the nail into a board; when it is hard to conceive any weight so great as will produce a like effect, *i. e.* that will sink the nail as far into the board, at least unless it is left to act for a very considerable time; and even after the greatest weight has been laid as a pressure on the head of the nail, and has sunk it as far as it can as to sense, by remaining for a long time there without producing any farther sensible effect; let the weight be removed from the head of the nail, and instead of it, let it be struck a small blow with a hammer, and the nail will immediately sink farther into the wood. Again, it is also well known, that a ship-carpenter, with a blow of his mallet, will drive a wedge in below the greatest ship whatever, lying aground, and so overcome her weight, and lift her up. Lastly, let us consider a man with a club to strike a small ball, upwards or in any other direction; it is evident that the ball will acquire a certain determinate velocity by the blow, suppose that of 10 feet per second or minute, or any other time whatever; now it is a law, universally allowed in the communication of motion, that when different bodies are struck with equal forces, the velocities communicated are reciprocally as the weights of the bodies that are struck; that is, that a double body, or weight, will acquire half the velocity from an equal blow; a body ten times as great, one-tenth of the velocity; a body 100 times as great, the 100th part of the velocity; a body a million times as great, the millionth part of the velocity, and so on, without end; from whence it follows, that there is no body or weight, how great soever, but will acquire some finite degree of velocity, and be overcome, by any given small finite blow, or percussion.

In percussion, we distinguish at least three several sorts of bodies; the perfectly hard, the perfectly soft, and the perfectly elastic. The two former are considered as utterly void of elasticity; having no force to separate or throw them off from each other again, after collision; and therefore either remaining at rest, or elseproceeding uniformly forward together as one body or mass of matter.

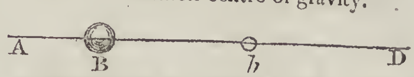
The laws of percussion therefore to be considered, are of two kinds; those for elastic, and those for non-elastic bodies.

The one only general principle for determining the motions of bodies from percussion, and which belongs equally to both the sorts of bodies, *i. e.* both the elastic and non-elastic, is this; viz. that there exists in the bodies the same momentum, or quantity of motion, estimated in any one and the same direction, both before the stroke and after it. And this principle is the immediate result of the third law of nature or motion, that reaction is equal to action, and in a contrary direction; from whence it happens, that whatever motion is communicated to one body by the action of another, exactly the same motion does this latter lose in the same direction, or exactly the same does the former communicate to the latter in the contrary direction.

From this general principle too it results, that no alteration takes place in the common centre of gravity of bodies by their actions upon another; but that the said common centre of gravity perseveres in the same state, whether of rest or of uniform motion, both before and after the shock of bodies.

Now, from either of these two laws, viz. that of the preservation of the same quantity of motion, in one and the same direction, and that of the preservation of the same state of the centre of gravity, both before and after the shock, all the circumstances of the motions of both the kinds of bodies after collision may be made out; in conjunction with their own peculiar and separate constitutions, namely, that of the one sort being elastic, and the other non-elastic.

The effects of these different constitutions, here alluded to, are these: that non-elastic bodies, on their shock, will adhere together, and either remain at rest, or else move together as one mass with a common velocity; or if elastic, they will separate after the shock, with the very same relative velocity with which they met and shocked. The former of these consequences is evident, viz. that non-elastic bodies keep together as one mass after they meet; because there exists no power to separate them, and without a cause there can be no effect. And the latter consequence results immediately from the very definition and essence of elasticity itself, being a power always equal to the force of compression or shock; and which restoring force therefore, acting the contrary way, will generate the same relative velocity between the bodies, or the same quantity of matter, as before the shock, and the same motion also of their common centre of gravity.



To apply now the general principle to the determination of the motions of bodies after their shock; let B and *b* be any two bodies, and V and *v* their respective velocities, estimated in the direction AD; which quantities V and *v* will be both positive if the bodies both move towards D, but one of them as *v* will be negative if the body *b* moves towards A, and *v* will be $= 0$ if the body *b* is at rest. Hence then, BV is the momentum of B towards D, and also *bv* is the momentum of *b* towards D, whose sum is $BV + bv$, which is the whole quantity of motion in the direction AD, and which momentum must also be preserved after the shock.

Now, if the bodies have no elasticity, they will move together as one mass $B + b$ after they meet, with some common velocity, which call y, in the direction AD: therefore the momentum in that direction after the shock, being the product of the mass and velocity, will be $(B + b) \times y$. But the momenta, in the same direction, before and after the impact, are equal, that is, $BV + bv = (B + b)\,y$; from which equation any one of the quantities may be determined when the rest are given. So, if we would find the common velocity after the stroke, it will be $y = \frac{BV + bv}{B + b}$, equal to the sum of the momenta divided by the sum of the bodies; which is also equal to the velocity of the common centre of gravity of the two bodies, both before and after the collision. The signs of the terms, in this value of y, will be all positive, as above, when the bodies move both the same way AD; but one term bv must be made negative when the motion of b is the contrary way; and that term will be absent or nothing, when b is at rest before the shock.

Again, for the case of elastic bodies, which will separate after the stroke, with certain velocities, x and z, viz. x the velocity of B, and z the velocity of b after the collision, both estimated in the direction AD, which quantities will be either positive, or negative, or nothing, according to the circumstances of the masses B and b, with those of their celerities before the stroke. Hence then, Bx and bz are the separate momenta after the shock, and $Bx + bz$ their sum, which must be equal to the sum $BV + bv$ in the same direction before the stroke: also $z - x$ is the relative velocity with which the bodies separate after the blow, and which must be equal to $V - v$, the same with which they meet; or, which is the same thing, that $V + x = v + z$; that is, the sum of the two velocities of the one body, is equal to the sum of the velocities of the other, taken before and after the stroke; which is another notable theorem. Hence then, for determining the two unknown quantities x and z, there are these two equations, viz.

$$BV + bv = Bx + bz,$$
and $$V - v = z - x;$$
or $$V + x = v + z;$$

the resolution of which equations gives those two velocities as below,

$$\text{viz. } x = \frac{2bv + (B - b)V}{B + b},$$

$$\text{and } z = \frac{2BV - (B - b)v}{B + b}.$$

From these general values of the velocities, which are to be understood in the direction AD, any particular cases may easily be drawn. As, if the two bodies B and b are equal, then $B - b = 0$ and $B + b = 2B$, and the two velocities in that case become, after impulse, $x = v$, and $z = V$, the very same as they were before, but changed to the contrary bodies, i. e. the bodies have taken each other's velocity that it had before, and with the same sign also. So that, if the equal bodies were before both moving the same way, or towards D, they will do the same after, but with interchanged velocities. But if they before moved contrary ways, B towards D, and b towards A, they will rebound contrary ways, B back towards A, and b towards D, each with the other's velocity. And, lastly, if one body, as b, was at rest before the stroke, then the other B will be at rest after it, and b will go on with the motion that B had before. And thus may any other particular cases be deduced from the first general values of x and z.

PERDICIUM, a genus of the class and order syngenesia polygamia superflua. The corollets are bilabiate; down simple; receptacle naked. There are six species.

PERENNIAL, in botany, is applied to those plants whose roots will abide many years, whether they retain their leaves in winter or not; those which retain their leaves are called evergreens; but such as cast their leaves, are called deciduous.

PERGALESIA, a genus of the pentandria digynia class and order. Contorted nect. surrounding the genitals with five-sagittated cups; corolla salver-shaped. There are five species, twining plants of the Cape, &c.

PERIANTHIUM. See BOTANY.

PERICARDIUM. See ANATOMY.

PERICARPIUM, among botanists, a covering or case for the seeds of plants. See BOTANY.

PERICRANIUM. See ANATOMY.

PERIGÆUM, PERIGEE. See ASTRONOMY.

PERIHELIUM. See ASTRONOMY.

PERILLA, a genus of the class and order didynamia gymnospermia. The calyx uppermost; segment very short; stamina distant; styles two, connected. There is one species, an annual of the East Indies.

PERIMETER, in geometry, the bounds or limits of any figure or body. The perimeters of surfaces or figures are lines, those of bodies are surfaces. In circular figures, instead of perimeter, we say circumference, or periphery.

PERINÆUM, or PERINEUM. See ANATOMY.

PERIOD, in astronomy, the time taken up by a star or planet in making a revolution round the sun; or the duration of its course till it returns to the same point of its orbit. See ASTRONOMY.

PERIOD. See CHRONOLOGY.

PERIOD, in grammar, denotes a small compass of discourse, containing a perfect sentence, and distinguished at the end by a point, or full stop, thus (.); and its members or divisions marked by commas, colons, &c.

PERIŒCI. See GEOGRAPHY.

PERIOSTEUM. See ANATOMY.

PERIPHERY, in geometry, the circumference of a circle, ellipsis, or any other regular curvilinear figure. See CIRCLE, &c.

PERIPLOCA, *Virginian silk*, a genus of the digynia order, in the pentandria class of plants; and in the natural method ranking under the 30th order, contortæ. The nectarium surrounds the genitals, and sends out five filaments. There are 13 species, some of which are natives of warm climates: one, however, is sufficiently hardy for this climate. The periploca is a fine climbing plant, that will wind itself with its ligneous branches about whatever tree, hedge, pale, or pole, is near it, and will arise, by the assistance of such support, to the height of above 30 feet; and where no tree or support is at hand to wind about, it will knit or entangle itself together in a most complicated manner. The stalks of the older branches, which are most woody, are covered with a dark-brown bark, whilst the younger shoots are more mottled with the different colours of brown and grey, and the ends of the youngest shoots are often of a light green. The leaves are the greatest ornament to this plant, for they are large, and of a shining green colour on their upper surface, and cause a variety by exhibiting their under surface of a hoary cast. Their figure is oblong, or rather more inclined to the shape of a spear, as their ends are pointed, and they stand opposite, by pairs, on short footstalks. Their flowers afford pleasure to the curious examiner of nature. Each of them singly has a star-like appearance; for, though it is composed of one petal only, yet the rim is divided into segments, which expand in such a manner as to form that figure. Their inside is hairy, as is also the nectarium which surrounds the petal. The propagation of this climber is very easy; for, if the cuttings are planted in a light moist soil, in the autumn or in the spring, they will readily strike root.

PERIPNEUMONY. See MEDICINE.

PERIPTERE. See ARCHITECTURE.

PERISCII. See GEOGRAPHY.

PERISTALTIC. See PHYSIOLOGY.

PERISTYLE. See ARCHITECTURE.

PERITONÆUM. See ANATOMY.

PERITROCHIUM. See MECHANICS.

PERJURY, is a crime committed when a lawful oath is administered, by any one who has authority, to a person in any judicial proceeding, who swears wilfully, absolutely, and falsely, in a matter material to the issue or cause in question, by his own act, or by the subornation of others. To constitute perjury, it is essential that the oath is wilfully taken; that it is in a judicial proceeding, or some other public proceeding of a similar nature: the oath must be taken before persons lawfully authorized to administer it, and also by a person sworn to depose the truth; it must also be taken absolutely and directly, and upon something material to the point in issue. It is not material whether the false oath is credited or not; or whether the party in whose prejudice it was taken, was in the event damaged by it; for the prosecution is not grounded upon the damage, but on the abuse of public justice. By stat. 5 Eliz. c. 9, persons guilty of perjury, or subornation of perjury, are to be punished with one year's imprisonment, and stand in the pillory where the offence was committed. This offence is also punished by transportation.

PERIWINKLE. See TURBO.

PERMUTATION *of quantities*, in algebra. See COMBINATION.

PERORATION. See RHETORIC.

PEROTIS, a genus of the digynia order, in the triandria class of plants, and in the natural method ranking under the fourth order, gramina. There is no calyx; the corolla consists of a bivalvular glume; the valves are oblong, acute, somewhat unequal, and terminating in a sharp beard. There are two species, natives of the East Indies.

PEROXIDE, in chemistry, denotes the maximum of oxidizement. See OXIDE.

PERPENDICULAR. See GEOMETRY.

PERPENDICULAR *to a parabola*, is a right line cutting the parabola in the point in which any other right line touches it, and is also itself perpendicular to that tangent.

PERPETUITY, in annuities, the number of years purchase to be given for an annuity which is to continue for ever. It is found by dividing 100*l*. by the rate of interest, and, consequently, is, at the most usual rates, as follows:

At 3 per cent.	33,3333
$3\frac{1}{2}$	28,5714
4	25,0000
$4\frac{1}{2}$	22,2222
5	20,0000
6	16,6666
	14,2857

These are the number of years purchase to be given for a perpetual annuity, on the supposition that it is receivable yearly; but as annuities are much more commonly receivable half-yearly, and the interest of money is likewise usually paid half-yearly, the perpetuity under these circumstances will be greater or less than the above, as the periods at which the annuity is payable are more or less frequent than those at which the rate of interest is supposed payable. Example at 4 per cent. interest:

Interest payable.	Annuity payable. Yearly.	Half-yearly.
Yearly,	25,000000	25,247548
Half-yearly,	24,752475	25,000000
Quarterly,	24,628109	24,875621

PERPETUITY is, where if all that have interest join in the conveyance, yet they cannot bar or pass the estate; for, if by concurrence of all having interest, the estate may be barred, it is no perpetuity. 1 Chan. Ca. 213.

PERRON. See ARCHITECTURE.

PERRY, a drink made of pears, in the same manner as cyder is made from apples. See CYDER.

PERSECUTION, is any pain or affliction which a person designedly inflicts upon another; and, in a more restrained sense, the sufferings of Christians on account of their religion. Historians usually reckon ten general persecutions, the first of which was under the emperor Nero, thirty-one years after our Lord's ascension; when that emperor having set fire to the city of Rome, threw the odium of that execrable action on the Christians, who under that pretence were wrapped up in the skins of wild beasts, and worried and devoured by dogs; others were crucified, and others burnt alive. The second was under Domitian, in the year 95. In this persecution St. John the apostle was sent to the isle of Patmos, in order to be employed in digging in the mines. The third began in the third year of Trajan, in the year 100, and was carried on with great violence for several years. The fourth was under Antoninus the philosopher, when the Christians were banished from their houses, forbidden to shew their heads, reproached, beaten, hurried from place to place, plundered, imprisoned, and stoned. The fifth began in the year 197, under the emperor Severus. The sixth began with the reign of the emperor Maximinus in 235. The seventh, which was the most dreadful persecution that had ever been known in the church, began in the year 250, in the reign of the emperor Decius, when the Christians were in all places driven from their habitations, stripped of their estates, tormented with racks, &c. The eighth began in the year 257, in the fourth year of the reign of the emperor Valerian. The ninth was under the emperor Aurelian, A. D. 274, but this was very inconsiderable; and the tenth began in the nineteenth year of Dioclesian, A. D. 303. In this dreadful persecution, which lasted ten years, houses filled with Christians were set on fire, and whole droves were tied together with ropes, and thrown into the sea.

PERSEUS, in astronomy, a constellation of the northern hemisphere, which, according to the catalogues of Ptolemy and Tycho, contains twenty-nine stars; but in the Britannic catalogue sixty-seven.

PERSIAN WHEEL, an engine, or wheel, turned by a rivulet, or other stream of water, and fitted with open boxes at its cogs, to raise water for the overflowing of lands, or other purposes. See HYDRAULICS.

It may be made of any size, according to the height the water is to be raised to, and the strength of the stream by which it is turned. This wheel is placed so that its bottom only is immersed in the stream, wherein the open boxes at its cogs are all filled one after another with water, which is raised with them to the upper part of the wheel's circuit, and then naturally empties itself into a trough which carries it to the land.

PERSICARIA, *arsmart.* See POLYGONUM.

PERSON, in grammar, a term applied to such nouns or pronouns, as being either prefixed or understood, are the nominatives in all inflections of a verb; or it is the agent or patient in all finite and personal verbs.

PERSONAL GOODS. See CHATTELS.

PERSONATE, is the representing a person by a fictitious or assumed character, so as to pass for the person represented. Personating bail, is by stat. 21 Jac. I. c. 26, a capital felony. By various other statutes, personating seamen entitled to wages, prize-money, &c. is also a capital felony.

PERSOONIA, a genus of the class and order tetrandria monogynia. There is no calyx; petals four; glands four, at the base of the germ; stigma blunt; drupe one-seeded.

PERSPECTIVE, is the art of drawing the picture or representation of any visible object on a plane surface, in such manner as it would appear on some transparent surface, interposed between an object and the eye of an observer. Hence it is the foundation of true painting, and is so far necessary in regulating the practical designs of an artist, that, without a knowledge of the principles thereof, he works at random, in not keeping to the nicety of measures and proportions. It has geometry for its foundation, and, consequently, truth for its support. It consists in determining and fixing the geometric situation of points in a picture, which points connected, produce lines, and lines (straight and curvilineal) constitute the first principles of a picture, the grand outline and structure which the painter is to dress with light and shade. Hence it is perceivable that the mathematician directs the outlines, but does not finish the piece; and, on the other hand, the painter cannot make a sure beginning without the mathematician's rules.

We do not mean to say that these rules are to be applied to the minute inflections or curvatures of every leafy subject of a landscape, or to all the smaller hollows and prominences of objects, or the muscular roundness and softness of living creatures; for these, as well as some other of the minutiæ of art, are to be determined by the eye, and drawn by a steady hand. A landscape-painter may study nature in the inmost recesses of a forest, and there store his mind with models of trees, shrubs, and foliage, and by such means he may become qualified to make a random picture of an individual shrub, or a group of trees; but if he would go further and represent a true protraiture of an avenue of these subjects, he must study the perspective diminution of the most remote parts thereof, as well as their relative positions, or his proposed picture will become an anamorphosis. He may give a tolerable direct view of one side of a building, but he can do no more; if he would give the representation of more than one side he must have recourse to the principles of perspective.

The practical rules of perspective are in great measure applied to the delineation of architectural bodies, and other right-lined figures; and a knowledge of the general laws of this science is sure to inform the judgment of the manner in which lines should run, whereto they should tend, and where terminate, so as to produce the desired effect.

Perspective is employed both in representing the ichnographies and the scenographics of objects; and the former is frequently found to be a necessary foundation of the latter.

We mean not to enter into an elaborate history of perspective, and say who it was that first discovered the properties of lines, which, when posited in certain order, would aid the representation of solid bodies, but rather proceed immediately to the practical rules, after premising that all the practical geometry necessary in this art has been elucidated in our preceding volume under that head, to which we refer the student.

The drawing-board, covered with a sheet of paper, may be termed the perspective plane, whereon the objects are to be delineated. See Plate Perspective, fig. 1.

Parallel to the bottom of this plane let a pencil-line be drawn, mark it AB, and call it the ground-line.

At about a third part, or somewhat more, of the height of the intended picture, or principal figure in the picture, draw (with the help of a T square) a pencil-line parallel to the ground-line, mark it *ho*, and call it the horizontal line. The height of this line will be variable, as the ground on which the observer stands may be higher or lower from the base of the principal figure; but, in general, when the draughtsman can choose his station, the height we have prescribed will be found the most convenient.

On that part of the ground-line which the eye is supposed opposite to in drawing any picture, draw another pencil-line perpendicular thereto, as at C, crossing the horizontal line at D. This point D is called the point of sight, being the spot which the eye is immediately opposite to, both in lateral and perpendicular position.

The ground-line, and its perpendicular, may be divided into scales of equal parts, whereof CD may be supposed five feet, the height of the eye.

The distance of the eye from the principal object must be set off in the horizontal line, both ways from the point of sight D. The choosing a proper distance is so essential a requisite, that, without a due observance thereof, a faithful representation of a picturesque object cannot be attained.

The most favourable point of distance seems to be that which is a mean between the diagonal of an upper quarter of the picture (as DG) set off from D to the perpendicular DE, continued as at *x*, and the length of the picture set off from G to the perpendicular, as at *y*; and the mean of the distance will be found at *z*, which will be somewhat about four times the height of the eye. This distance must be set off on the horizontal line also, as before mentioned, on one or both sides of the point of sight.

These requisites being laid down on the drawing-board, we may proceed to examples of finding the true positions of points and lines on the picture, from their ichnography, drawn out of, and below, the base line.

Suppose the pentagon ABDEF (fig. 2.) was to be represented by the rules of perspective on the transparent plane VP, placed perpendicularly on the horizontal plane HR; dotted lines are imagined to pass from the eye C to each point of the pentagon, as CA, CB, CD, &c. which are supposed in their passage through the plane PV, to leave their traces or vestigia in the points *a*, *b*, *d*, &c. on the plane, and thereby to delineate the pentagon *abdef*; which, as it strikes the eye by the same rays that the original pentagon ABDEF does, will be a true perspective representation of it.

The business of perspective, therefore, is to lay down geometrical rules for finding the points *abdef* upon the plane; and hence, also, we have a mechanical method of delineating any object very accurately.

Perspective is either employed in representing the ichnographics, or ground-plots of objects; or the scenographics, or representations of the objects themselves.

But before we give any examples of either, it will be proper to explain some technical terms in regard to perspective in general; and, first, the horizontal line is that supposed to be drawn parallel to the horizon through the eye of the spectator; or rather it is a line which separates the heaven from the earth, and which limits the sight. Thus, A, B, fig. 3, are two pillars below the horizontal line CD, by reason the eye is elevated above them; in fig. 4, they are said to be equal with it; and in fig. 5, raised above it. Thus, according to the different points in view, the objects will be either higher or lower than the horizontal line. The point of sight, A, fig. 6, is that which makes the central ray on the horizontal line; or, it is the point where all the other visual rays, D, D, unite. The points of distance, C, C, are points set off in the horizontal line at equal distances on each side of the point of sight, A; and, in the same figure, BB represents the base line, or fundamental line; EE is the abridgment of the square, of which D, D, are the sides; F, F, the diagonal lines, which go to the points of distance C, C. Accidental points, are those where the objects end: these may be cast negligently, because neither drawn to the point of sight, nor to those of distance, but meeting each other in the horizontal line. For example, two pieces of square timber, G and H, fig. 7, make the points I, I, I, I, on the horizontal line; but go not to the point of sight K, nor to the points of distance C, C: these accidental points serve likewise for casements, doors, windows, tables, chairs, &c. The point of direct view, or of the front, is when we have the object directly before us; in which case, it shews only the foreside; and, if below the horizon, a little of the top, but nothing of the sides, unless the object is polygonous. The point of oblique view, is when we see an object aside of us, and as it were aslant, or with the corner of the eye; the eye, however, being all the while opposite to the point of sight; in which case, we see the object laterally, and it presents to us two sides or faces. The practice is the same in the side-points, as in the front-points; a point of sight, points of distance, &c. being laid down in the one as well as in the other.

We shall now give some examples, by which it will appear that the whole practice of perspective is built upon the foundation already laid down. Thus, to find the perspective appearance of a triangle, ABC, fig. 8, between the eye and the triangle draw the line DE, which is called the fundamental line; from 2 draw 2 V, representing the perpendicular distance of the eye above the fundamental line, be it what it will; and through V draw, at right angles to 2 V, HH parallel to DE: then will the plane DHHE represent the transparent plane, on which the perspective representation is to be made. Next, to find the perspective points of the angles of the triangle, let fall perpendiculars A 1, C 2, B3, from the angles to the fundamental DE: set off these perpendiculars upon the fundamental opposite to the point of distance H, to B, A, C; from 1, 2, 3, draw lines to the principal point V; and from the points A, B, and C, on the fundamental line, draw the right lines AH, BH, CH, to the point of distance H; which is so called, because the spectator ought to be so far removed from the figure or painting, as it is distant from the principal point V. The points *a*, *b*, and *c*, where the visual lines V 1, V 2, V 3 intersect the lines of distance AC, BH, CH, will be the angular points of the triangle *abc*, the true representation of ABC.

By proceeding in this manner with the angular points of any right-lined figure, whether regular or irregular, it will be very easy to represent it in perspective; however, in practice, several compendious methods will occur to every artist. Again, if the scenographic appearance of any solid was to be represented, suppose of a triangular prism, whose base is the triangle *mno*, fig. 9, you need only find the upper surface of it, in the same manner as you found the lower, or base; and then joining the corresponding points by right lines, you will have the true representation of the solid in perspective. So that the work is the same as before; only you take a new fundamental line, as much higher than the former, as is the altitude of that solid whose scenographic representation you would delineate.

But there is still a more commodious way, which is this: having found, as above, the base or ichnographic plane *mno*, let perpendiculars be erected to the fundamental line from the three angular points, which will express the altitudes of those points. But because these altitudes, though equal in the body or solid itself, will appear unequal in the scenographic view, the farthest off appearing less than those nearer the eye, their true proportional heights may be thus determined. Any where in the fundamental line, let AB be erected perpendicularly, and equal to the true altitude; or, if the figure has different altitudes, let them be transferred into the perpendicular AB; and from the points A and B, and from all the points of intermediate altitudes, if there are any such, draw right lines to the point of sight V: those lines, AV, BV, will constitute a triangle with AB, within which all the points of altitude will be contained. Through the points *o*, *n*, *m*, draw parallels to the fundamental line; and from the points *a*, *a*, &c. erect perpendiculars to those parallels; and the points where they intersect the lines AV, BV, as in *a*, *a*, *b*, *b*, &c. will determine the apparent height of the solid in that scenographic position to the eye in V.

Parallel perspective is where the picture is supposed to be so situated, as to be parallel to the side of the principal object in the picture, as a building for instance. Then the lines on those sides of the building that are parallel to each other, continue parallel on the picture, and do not vanish into any point; while the lines at right angles to the former, vanish into the centre of the picture. This will be exemplified in fig. 10.

The picture being supposed to stand parallel to the side of the house ABCD, the lines AB, DC, which in nature are parallel to each, must be made parallel in the perspective representation. But the lines BE, CF, which in nature are at right angles to AB and DC, and consequently also to the picture, tend towards a point; and this point G, towards which they tend, is the centre of the picture.

Oblique perspective, is when the plane of the picture is supposed to stand oblique to the sides of the objects represented, in which case the representations of the lines upon those sides will not be parallel among themselves, but will tend towards their vanishing point. This kind of perspective is shewn in fig. 11.

A bird's-eye view, is a view supposed to be taken in the air, looking down upon the object, and differs from the usual way of drawing perspective views, in supposing the horizontal line to be raised much higher.

When an object is to be drawn in perspective, all its parts must be measured, so that we may be able to lay them down from a scale of equal parts.

Having determined whether it is to be parallel or oblique perspective, the first thing to be drawn is the horizontal line, which is to be put parallel to the bottom of the drawing, and as high above it as the height of a man's head, or five feet six inches, as HG, fig. 10, which is five feet six inches above the bottom of the house. Next, determine on the centre of the picture G, which must be placed so as to leave convenient room for the representation. Fix on C the nearest corner of the object, and draw the perpendicular CB: lay off CD equal to the length of the building, and draw DA and AB. From C, the nearest corner, draw CG, to the centre of the picture. CG now contains the line which represents the bottom of the end of the house; but this is an indefinite representation, of which we do not yet know the exact length. The method of determining this is as follows: Continue the line DC to I, and make CI equal to the width of the house. From G, the centre of the picture, lay off GK equal to the distance of the picture, the choosing of which must be regulated by taste. Draw IK, cutting CG in F; then is CF the exact width of the house in perspective, which was equal to CI. To find the middle of this end of the house, you cannot divide it by your compasses, because the farthest half will appear less than the nearer; but if you divide CI into two equal parts in L, and draw LK, it will cut CF into two equal parts perspectively. Or it may be found more simply thus: having drawn the lines BE and CF to the centre of the picture, draw the diagonals EC, BF, crossing each other in M, and raise the perpendicular MN, which is in the middle of the gable-end.

To find the height of the gable, lay its actual height above BE, upon the corner line BC continued, as BO, and draw OG; this crossing the perpendicular MN, gives N the point of the gable. The top of the chimney must be drawn in the same manner, by laying its real height, taken from a scale, on OP; and drawing PG, lay off L*m* and L*n*, each equal to half the width, and draw from these points to the distance-point K; this will cut the bottom of the house CF, in the points *o* and *p*; from these draw perpendiculars, which will give the perspective width of the chimney. To obtain its thickness, lay off PQ equal to its thickness, and draw QG; then drawing from *a* the line *ab*, you obtain the exact width of the chimney. From *b* draw *bc*, and from *d* draw *dc*. The other end of the gable may be drawn by two different methods. The first is by supposing the front of the house transparent, and drawing the other end as if seen through it, in the same manner as the end we have described, by laying its width from D to R, and drawing to the distance-point K. By raising the perpendicular in the middle, you will meet the ridge-line from the other gable in *d*. The other method is as follows: Through the centre of the picture G draw the line ST, upwards and downwards, and perpendicular to the horizontal line. Then continue the line of the roof B*d* till it meets ST in S. From A draw AS, which will give the other gable, and S will be the vanishing-point for all lines parallel to B*d* and A*d*; if NE is continued in like manner, it will give T for its vanishing-point. The doors and windows on the side ABCD are laid down from a scale, because that side being parallel to the picture, does not vary from its geometrical delineation, except shewing the thickness of the reveals, or edges of the doors and windows. If there had been any windows in the side BEFC, they would be drawn in perspective by the same method that was used for finding the width of the house and the middle of the end, viz. by laying off the actual dimensions from C upon CI, and drawing from these points to the distance-point K, which would transfer these divisions to the bottom of the house CF, and then perpendiculars might be drawn upwards.

This practice is farther explained by the following rule:

To divide a line in perspective which is parallel to the horizon, and which tends to a vanishing-point, into any number of equal parts; or to divide it into any required proportion.

Let AB be the line going to its vanishing-point C, fig. 12; and first let it be required to divide that line into six equal parts. Let CD be the horizontal line, and AE the ground-line, drawn parallel to it. Lay off, at pleasure, CD for the distance of the picture, if C is the centre of tne picture. Draw a line from D, touching the end B of the line to be divided: draw DBE, cutting the ground-line in E. Then AE represents the actual dimensions of the line AB, which is seen in perspective. (Here it may be observed, that this gives a rule also for finding the real length of any line which tends to a vanishing-point.) Divide AE into the same number of equal parts into which you proposed to divide the given line AB; as A1, 1 2, 2 3, &c. Then from these different divisions draw lines to D, cutting the line AB in *a*, *b*, *c*, *d*, &c. which will represent the required number of equal parts, but diminishing in size as they are farther removed from the eye. If it is wished to divide the line AB into any number of unequal parts, or to lay off doors, windows, &c. upon it, the line AE, found as before, must be divided in the required propoıtion, and lines drawn from those to D will give the required divisions on AB, from which perpendiculars may be drawn for the doors, windows, &c.

To draw a circle in perspective.

The perspective representation of every circle is a regular ellipsis, when the eye is without the circle; which may be demonstrated by considering that the rays from the circumference of the circle to the eye, form an oblique cone. But it is well known to those who are acquainted with conic sections, that every section of a cone, whether right or oblique, is a true ellipsis, except in one case only, which is, when the section is taken subcontrary to its base, a situation which happens so rarely in drawings that it may be disregarded altogether, and the section of a cone, or the perspective of a circle, in all cases considered as a perfect ellipsis.

The most correct and easy method of drawing an ellipsis is, to find the transverse and conjugate axes; the curve may then be completed by a trammel, or by hand. But as it is very difficult to find the transverse and conjugate axes of the ellipses which are the perspective representations of circles, recourse is generally had to another method of obtaining the curve. The circle is circumscribed by a square, as KLMN, in fig. 13, and the diagonals and the lines across the centre, and parallel to the sides, are drawn; also the lines *al*, *cd*, are drawn parallel to the sides, through the points where the circle is cut by the diagonals. This square, with all these lines drawn across it, is now put in perspective as follows: Draw AB for the horizontal line, and fix B for the centre of the picture, and AB for the distance of the picture. Make DC equal to the width of the square, and draw CB, DB; draw CA to the distance-point A, cutting off DG, equal to the depth of the square; then draw GF parallel to DC, which completes the perspective of the square; also draw the diagonal DF. Take now the distances M*a*, *c*N; and transfer them to D*x*, *o*C; from these points *x* and *o*, draw lines to the vanishing-point B, cutting the diagonals of the square. The points in this reticulated square in perspective, which correspond to those in the square KLMN, where the circle passes through, must now be observed, and a curve traced through them with a steady hand it will be the perspective required. Even in this process, it is of considerable use to know that the curve you are tracing is a regular ellipsis: for though you cannot easily ascertain the axes exactly, yet you may very nearly; and the eye very soon discovers whether the curve which has been drawn is that of a regular ellipsis or not.

Upon the same principle exactly, the row of arches, fig. 14, is drawn. The width of the arches and piers is obtained in the same manner as was shewn in fig. 12, viz. by laying their dimensions upon the ground-line AB, and drawing lines to the distance-point. The curves of the arches are then found by drawing the lines which correspond to those in half the square, fig. 13, in the same manner as described above for the circle.

Fig. 15 shews the appearance of circles drawn upon a cylinder, when HI is the horizontal line. The circle drawn on the cylinder at that place, is seen exactly edgeways, and appears only as a straight line; that next above it is seen a little underneath; the next still more; and so on, as they rise higher, appearing like so many ellipses of the same transverse diameter, but whose conjugate diameters continually increase in length, as they rise above the horizontal line. On the contrary, you see the under sides of the circles drawn below the horizontal lines; but they observe the same law, being so many ellipses, whose conjugate diameters vary in the same proportion. A little reflection on this simple example, will enable those who draw to avoid many ridiculous mistakes which are sometimes committed; such as shewing the two ends of a cask, or the top and bottom of a cylinder, at the same time.

Fig. 11 shews the method of drawing a building, or other object, in oblique perspective. AB is the horizontal line, and CD the ground-line, parallel to it as before. Here neither of the sides of the house is parallel to the picture, but each goes to its respective vanishing-point. Having fixed on the nearest corner E, draw EB, at pleasure, for one side, and choose any point F for the centre of the picture; then, to find the other side, lay off FG equal to the distance of the picture, which, as before, depends upon taste only; draw BG, and GA perpendicular to BG, cutting the horizontal line in A, the other vanishing-point. Draw now EA for the other side. To cut off the several widths of the two sides of the house, which as yet are only drawn to an indefinite extent, two distance-points must be laid down, viz. one for each vanishing-point. To do this, extend the compasses from B to G, and lay the distance taken in it from B to H, which will give H for the distance-point of B, and which is to cut off all the divisions on the side EB. Also extend the compasses from AG, and lay down AI. I is the distance-point of A, and is used for transferring all divisions upon the side EA from the ground-line GE. These points and lines being adjusted, the process is not much different from parallel perspective; only here equal divisions on each side of the building, as doors, windows, diminish as they recede in the same way as on the side BEFC, fig. 10. Lay the real length of the side EL, taken from the same scale used for laying down the horizontal line, and lay it down on the ground-line, from E to C, and draw CI, cutting off EL for the perspective length of the building. For the other side of the house, lay its width down in the same manner, from E to D, and draw DH, cutting off EN for the perspective width. Raise the perpendiculars EM, LK, and NO, for the three angles of the house. Lay the height of the building upon the corner that comes to the ground-line, as EM, and draw MK and MO to their several vanishing-points. Also lay all the heights of the doors and windows, and other divisions, upon EM, and draw them to the vanishing-points A and B. To lay down the widths of the doors and windows, put their actual widths upon CE, and draw from them to the distance-point I, which cuts off all divisions upon the side LE, and then raise the perpendiculars. The gable-end is found exactly in the same manner as has been described, only taking care to use the proper distance-point H. The manner of finding the width of the chimney is different. Lay off *ba* for the height of the chimney above the top of the gable, and draw *ac* parallel to the horizontal line; then put *ac* equal to the actual thickness of the chimney, and draw *ad* to the vanishing-point A; draw also *cd* to the distance-point I, cutting off *ad* in *d*: then having drawn *ef* from the nearest corner of the chimney, which was found as in fig. 10, draw *df* to the vanishing-point B, cutting off *ef* for the exact perspective width.

Fig. 16 represents the method of finding the perspective of a circle in oblique perspective. AB is the horizontal line, C the centre of the picture, and D, E, the distance-points. The process is exactly the same as that just described; the several divisions of the reticulated square in fig. 13, being laid upon the ground-line FG, and from these, lines are drawn to the distance-points. The perspective of the square is then drawn with all the lines across it, and the curve traced through the different points.

By drawing these examples frequently over, to a large scale, and reflecting upon them with attention, the student will become familiar with their use; and as they include the cases which most frequently occur, he will necessarily find great benefit from the knowledge of them.

The practical part of perspective, is only the application of these rules to the actual description of objects. But, as this part is purely mathematical, its assistance towards drawing is alone what can be performed by rule and compass, and can therefore strictly serve only for finding the images of points, of which they are composed; and, as these are infinite, it is endless to find them all by the strict rules; whence it becomes necessary after a sufficient number of them are found, to complete the image by the help of drawing, to the better effecting of which these points serve as a guide. Thus, when a circle is to be described, the practical rules serve to find a sufficient number of points in the circumference; which, being neatly joined by hand, will perfect the image, so that, in strictness, nothing in this image is found by mathematical rules, save the few particular points; the rest owes its being to the hand of the drawer.

Thus also, if any complicated figure is proposed, it may not be easy to apply the practical rules to the description of every minute part; but by inclosing that figure in a regular one, properly subdivided and reduced into perspective, that will serve as a help, whereby a person skilled in drawing, may with ease describe the object proposed. Upon the whole, where the boundaries of the proposed objects consist of straight lines and plane surfaces, they may be described directly by the rules of perspective; but when they are curvilinear, either in their sides or surfaces, the practical rules can only serve for the description of such right-lined cases as may conveniently inclose the objects, and which will enable the designer to draw them within those known bounds with a sufficient degree of exactness.

It is therefore in vain to seek, by the practical rules of perspective, to describe all the little hollows and prominences of objects, the different light and shade of their parts, or their smaller windings and turnings; the infinite variety of the folds in drapery; of the boughs and leaves of trees, or the features and limbs of men and animals; much less to give them that roundness and softness, that force and spirit, that easiness and freedom of posture, that expression and grace, which are requisite to a good picture. Perspective must content itself with its peculiar province of exhibiting a kind of rough draught to serve as a ground-work, and to ascertain the general proportions and places of the objects, according to their supposed situations; leaving the rest to be finished, beautified, and ornamented, by a hand skilful in drawing.

It is true, perspective is of most use where it is most wanted, and where a deviation from its rules would be the most observable; as in describing all regular figures, pieces of architecture, and other objects of that sort, where the particular tendency of the several lines is most remarkable; the rule and compass in such cases being much more exact than any description made by hand: but still the figure, described by the perspective rules, will need many helps from drawing; the capitals, and other ornaments of pillars, and their entablatures, the strength of light and shade, the apparent roundness and protuberance of the several parts, must owe their beauty and finishing to the designer's hand; but, with regard to such objects as have no constant and certain determinate shape or size, such as clouds, hills, trees, rivers, uneven grounds, and the like, there is a much larger latitude allowable, provided the general bulk, or usual natural shape of those objects, are in some measure observed, so as not to make them appear unnatural or monstrous. See DRAWING.

But, although the strict practical rules of perspective are in a great measure confined to the description of right-lined figures, yet the knowledge of the general laws of that science is of great and necessary use to inform the judgment, after what manner the images of any proposed lines should run, which way they should tend, and where terminate; and thereby enables it the better to determine what appearance any objects ought to put on, according to their different situations and distances; it accustoms the eye to judge with greater certainty of the relations between real objects and their perspective descriptions, and the hand to draw the same accordingly, and directs the judgment readily to discover any considerable error therein which might otherwise escape notice. Besides that, when the ground, or general plan, and the principal parts of a picture, are first laid down according to the rules, every thing else will more naturally fall in with them, and every remarkable deviation from the just rules will be the more readily perceived, and the easier avoided or rectified; so that although it may be infinitely tedious, or absolutely impracticable, to describe every minute part of a picture by the strict mechanical rules, yet the employing them, where they can be the most commodiously used, will give the picture in general such a look, as will guide the artist in drawing the other parts without any obvious inconsistency.

We shall, therefore, give such rules as are of most general use in the practice of perspective. 1. Let every line which in the object or geometrical figure is straight, perpendicular or parallel to its base, be so also in its scenographic delineation. 2. Let the lines, which in the object return at right angles from the fore-right side, be drawn scenographically from the visual point. 3. Let all straight lines, which in the object return from the fore-right side, run in a scenographic figure into the horizontal line. 4. Let the object you intend to delineate, standing on your right hand, be placed also on the right hand of the visual point; and that on the left hand, on the left hand of the same point; and that which is just before, in the middle of it. 5. Let those lines which are (in the object) equidistant to the returning line, be drawn in the scenographic figure, from that point found in the horizon. 6. In setting off the altitude of columns, pedestals, and the like, measure the height from the base-line upward, in the front or fore-right side; and a visual ray down that point in the front shall limit the altitude of the column or pillar, all the way behind the fore-right side, or orthographic appearance, even to the visual point. This rule you must observe in all figures, as well where there is a front or fore-right side, as where there is none. 7. In delineating ovals, circles, arches, crosses, spirals, and cross arches, or any other figure in the roof of any room, first draw it ichnographically; and so with perpendiculars from the most eminent points thereof, carry it up into the ceiling; from which several points carry on the figure. 8. The centre in any scenographic regular figure, is found by drawing cross lines from opposite angles: for the point where the diagonals cross, is the centre. 9. A ground-plane of squares is alike, both above and below the horizontal line; only the more it is distant above or beneath the horizon, the squares will be so much the larger or wider. 10. In drawing a perspective figure, where many lines come together, you may, for the directing of your eye, draw the diagonals in red: the visual lines in black; the perpendiculars in green, or other different colour from that which you intend the figure shall be of. 11. Having considered the height, distance, and position of the figure, and drawn it accordingly, with side or angle against the base, raise perpendiculars from the several angles or designed points, from the figure to the base; and transfer the length of each perpendicular, from the place where it touches the base, to the base on the side opposite to the point of distance; so will the diametrals drawn to the perpendiculars in the base, by intersection with the diagonals, drawn to the several transferred distances, give the angles of the figures, and so lines drawn from point to point will circumscribe the scenographic figure. 12. If in a landscape there are any standing waters, as rivers, ponds, and the like, place the horizontal line level with the farthest sight or appearance of it. 13. If there are any houses, or the like, in the picture, consider their position, that you may find from what point in the horizontal lines to draw the front and sides thereof. 14. In describing things at a great distance, observe the proportion both in magnitude and distance, in draught, which appears from the object to the eye. 15. In colouring and shadowing of every thing, you must do the same in your picture, which you observe with your eye, especially in objects lying near; but, according as the distance grows greater and greater, so the colours must be fainter and fainter, till at last they lose themselves in a darkish sky-colour. 16. The catoptrics are best seen in a common looking-glass, or other polished matter, where, if the glass is exactly flat, the object is exactly like its original: but, if the glass is not flat, the resemblance alters from the original; and that more or less, according as the glass differs from an exact plane. 17. In drawing catoptric figures, the surface of the glass is to be considered, upon which you mean to have the reflection: for which you must make a particular ichnographical draught or projection, which on the glass must appear to be a plane full of squares; on which projection transfer what shall be drawn on a plane, divided into the same number of like squares, where though the draught may appear very confused, yet the reflection of it on the glass will be very regular, proportional, and regularly composed. 18. The dioptric, or broken beam, may be seen in a tube through a crystal or glass which has its surface cut into many others, whereby the rays of the object are broken. For to the flat of the crystal, or water, the rays run straight; but then they break and make an angle, which also by the refracted beams is made and continued on the other side of the same flat. 19. When these faces on a crystal are returned towards a plane placed directly before it, they separate themselves at a good distance on the plane, because they are all directed to various far-distant places of the same.

Perspective plane, is the glass or other transparent surface, PV, (Plate Perspective, fig. 2.) supposed to be placed between the eye and the object, perpendicularly to the horizon. It is sometimes called the section, table, or glass.

PERSPIRATION. There seems to be something thrown out from the blood during its circulation in the arteries, at least through those vessels which are near the surface of the body: for it is a fact, that certain substances are constantly emitted from the skins of animals. These substances are known in general by the name of perspirable matter, or perspiration. They have a great resemblance to what is emitted in the lungs; which renders it probable that both excretions are owing to the same cause, namely, to the decomposition produced in the blood by the effects of respiration. Many experiments have been made to ascertain the quantity of matter perspired through the skin. For the first set, and not the least remarkable, we are indebted to Sanctorius, who continued them for no less than thirty years. He ascertained his own weight, and the weight of his food; and whatever weight he lost over and above that of his excrements, he ascribed to perspiration. A similar set of experiments was afterwards made in France by Dodart; in England by Keil; in Ireland by Bryan Robertson and Rye; and in Carolina by Lining. The result of all these experiments has been collected by Haller; but it gives us no precise estimate of the amount of the transpiration, since these philosophers have not distinguished between what is lost by the skin and by the lungs. Lavoisier and Seguin alone have attempted to ascertain the amount of the matter perspired through the skin. A bag composed of varnished silk, and perfectly air-tight, was procured, within which Seguin, who was usually the subject of experiment, was enclosed, and the bag was closed exactly over his head. There was a slit in the bag opposite to his mouth, and the edges of this slit were accurately cemented round the mouth by means of a mixture of turpentine and pitch. Thus every thing emitted by the body was retained in the bag, except what made its escape from the lungs by respiration. By weighing himself in a delicate balance at the commencement of the experiment, and again after he had continued for some time in the bag, the quantity of matter carried off by respiration was ascertained. By weighing himself without this varnished covering, and repeating the operation after the same interval of time had elapsed as in the former experiment, he ascertained the loss of weight occasioned by perspiration and respiration. By subtracting from this sum the loss of weight indicated by the first experiment, he obtained the quantity of matter which made its escape by perspiration in a given time. The following facts were ascertained by these experiments: 1. The maximum of matter perspired in a minute amounted to 26.25 grains troy; the minimum to 9 grains: which gives 17.63 grains at a medium in the minute, or 52.82 ounces in the 24 hours. This quantity differs less than might have been expected from the result of former experiments made by Dodart, Keil, Rye, &c. 2. The quantity perspired is increased by drink, but not by solid food. 3. Perspiration is at its minimum immediately after a repast. It reaches its maximum during digestion. See Digestion.

The quantity of matter perspired differs very considerably according to circumstances. It has been shewn to be greatest in hot weather, and in hot climates, and after great exercise; and its relation to the quantity of urine has been long known. When the matter perspired is great, the quantity of urine is small, and vice versa.

To ascertain the substance thus emitted by perspiration is a difficult task, because it passes off invisibly, and in small quantities at a time. It has, notwithstanding, been ascertained that water, carbon, and an oily matter, are emitted; and that an acid supposed to be the phosphoric, phosphat of lime, and even urea, are sometimes emitted through the skin.

1. The most accurate experiments on this matter that have been made are those of Mr. Cruikshank. He put his hand into a glass vessel, and luted its mouth at his wrist by means of a bladder. The interior surface of the vessel became gradually dim, and drops of water trickled down. By keeping his hand in this manner for an hour, he collected thirty grains of a liquid, which possessed all the properties of pure water. On repeating the same experiment at nine in the evening (thermometer 62°), he collected only 12 grains. The mean of these is 21 grains. But as the hand is more exposed than the trunk of the body, it is reasonable to suppose that the perspiration from it is greater than that from the hand. Let us therefore take 30 grains per hour as the mean; and let us suppose, with Mr. Cruikshank, that the hand is $\frac{1}{60}$th of the surface of the body. The perspiration in an hour would amount to 1880 grains, and in 24 hours to 43,200 grains, or 7 pounds 6 ounces troy. This is almost double the quantity ascertained by Lavoisier and Seguin. Hence we may conclude that more matter is perspired through the hand than the other parts of the body, provided Mr. Cruikshank's estimate of the ratio between the surface of the hand and body is not erroneous.

He repeated the experiment again after hard exercise, and collected in an hour 48 grains of water. He found also, that this aqueous vapour pervaded his stocking without difficulty; and that it made its way through a shamoy-leather glove, and even through a leather boot, though in a much smaller quantity than when the leg wanted that covering.

It is not difficult to see why the quantity of watery vapour diminishes with cold. When the surface of the body is exposed to a cold temperature, the capacity of the cutaneous vessels diminishes, and consequently the quantity which flows through them must decrease.

When the temperature, on the other hand, is much increased, either by being exposed to a hot atmosphere, or by violent exercise, the perspired vapour not only increases in quantity, but even appears in a liquid form. This is known by the name of sweat. In what manner sweat is produced, is not at present known; but we can see a very important service which it performs to the animal. No sooner is it thrown upon the surface of the skin than it begins to evaporate. But the change into vapour requires heat; accordingly a quantity of heat is absorbed, and the temperature of the animal is lowered. This is the reason that animals can endure to remain for some time in a much higher temperature without injury, than could have been supposed.

The experiments of Tillet, and the still more decisive experiments of Fordyce and his associates, are well known. These gentlemen remained a considerable time in a temperature exceeding the boiling-point of water.

2. Besides water, it cannot be doubted that carbon is also emitted from the skin; but in what state, the experiments hitherto made do not enable us to decide. Mr. Cruikshank found that the air of the glass vessel in which his hand and foot had been confined for an hour contained carbonic acid gas; for a candle burned dimly in it, and it rendered lime-water turbid. And Mr. Jurine found that air which had remained for some time in contact with the skin, consisted almost entirely of carbonic acid gas. The same conclusion may be drawn from the experiments of Ingenhousz and Milly. Trousset has lately observed that air was separated copiously from a patient of his while bathing.

Now it is evident that the carbonic acid gas which appeared during Mr. Cruikshank's experiment, did not previously exist in the glass vessel; consequently it must have either been transmitted ready-formed through the skin, or formed during the experiment by the absorption of oxygen gas, and the consequent emission of carbonic acid gas. The experiments of Mr. Jurine do not allow us to suppose the first of these to be true; for he found that the quantity of air allowed to remain in contact with the skin did not increase. Consequently the appearance of the carbonic acid gas must be owing either to the emission of carbon, which forms carbonic acid gas by combining with the oxygen gas of the air, or to the absorption of oxygen gas, and the subsequent emission of carbonic acid gas; precisely in the same manner, and for the same reason, that these substances are emitted by the lungs. The last is the more probable opinion; but the experiments hitherto made do not enable us to decide.

3. Besides water and carbon, or carbonic acid gas, the skin emits also a particular odorous substance. That every animal has a peculiar smell, is well known: the dog can discover his master, and even trace him to a distance by the scent. A dog, chained some hours after his master had set out on a journey of some hundred miles, followed his footsteps by the smell, and found him on the third day in the midst of a crowd. But it is needless to multiply instances of this fact; they are too well known to every one. Now this smell must be owing to some peculiar matter which is constantly emitted; and this matter must differ somewhat either in quantity or some other property, as we see that the dog easily distinguishes the individual by means of it. Mr. Cruikshank has made it probable that this matter is an oily substance; or at least that there is an oily substance emitted by the skin. He wore repeatedly, night and day for a month, the same vest of fleecy hosiery during the hottest part of the summer. At the end of this time he always found an oily substance accumulated in considerable masses on the nap of the inner surface of the vest, in the form of black tears. When rubbed on paper, it makes it transparent, and hardens on it like grease. It burns with a white flame, and leaves behind it a charry residuum.

4. Berthollet has observed the perspiration acid; and he has concluded that the acid which is present is the phosphoric: but that has not been proved. Fourcroy and Vauquelin have ascertained that the scurf which collects upon the skins of horses consists chiefly of phosphat of lime, and urea is even sometimes mixed with it. It is well known that the sweat has a salt taste; but hitherto it has not been analysed, though it probably differs from the transpiration.

It has been supposed that the skin has the property of absorbing moisture from the air; but this opinion has not been confirmed by experiments, but rather the contrary.

The chief arguments in favour of the absorption of the skin, have been drawn from the quantity of moisture discharged by urine being, in some cases, not only greater than the whole drink of the patient, but even the whole of his drink and food. But it ought to be remembered that, in diabetes, the disease here alluded to, the weight of the body is continually diminishing, and therefore part of it must be constantly thrown off. Besides, it is scarcely possible in that disease to get an accurate account of the food swallowed by the patients; and in those cases where very accurate accounts have been kept, and where deception was not so much practised, the urine was found to exceed the quantity of drink. In a case of diabetes, related with much accuracy by Dr. Gerard, the patient was bathed regularly during the early part of the disease in warm water, and afterwards in cold water: he was weighed before and after bathing, and no sensible difference was ever found in his weight. Consequently, in that case, the quantity absorbed, if any, must have been very small.

It is well known that thirst is much alleviated by cold bathing. By this plan captain Bligh kept his men cool and in good health during their very extraordinary voyage across the South Sea. This has been considered as owing to the absorption of water by the skin. But Dr. Currie had a patient who was wasting fast for want of nourishment, a tumour in the œsophagus preventing the possibility of taking food, and whose thirst was always alleviated by bathing; yet no sensible increase of weight, but rather the contrary, was perceived after bathing. It does not appear then, that in either of these cases water was absorbed. The allaying of thirst by the cold bathing may indeed easily be accounted for, by the lessening of the temperature, and the prevention of perspiration.

Further, Seguin has shewn that the skin does not absorb water during bathing, by a still more complete experiment: he dissolved some mercurial salt in water, and found that the mercury produced no effect upon a person that bathed in the water, provided no part of the cuticle was injured; but upon rubbing off a portion of the cuticle, the mercurial solution was absorbed, and the effects of the mercury became evident upon the body. Hence it follows irresistibly, that water, at least in the state of water, is not absorbed by the skin when the body is plunged into it, unless the cuticle is first removed.

This may perhaps be considered as a complete proof that no such thing as absorption is performed by the skin; and that therefore the appearance of carbonic acid gas, which takes place when air is confined around the skin, must be owing to the emission of carbon. But it ought to be considered, that although the skin cannot absorb water, this is no proof that it cannot absorb other substances; particularly that it cannot absorb oxygen gas, which is very different from water. It is well known that water will not pass through bladders, at least for some time: yet Dr. Priestley found that venous blood acquired the colour of arterial blood from oxygen gas, as readily when these substances were separated by a bladder, as when they were in actual contact. He found, too, that when gases were confined in bladders, they gradually lost their properties. It is clear from these facts, that oxygen gas can pervade bladders; and if it can pervade them, why may it not also pervade the cuticle? Nay, further, we know from the experiments of Cruikshank, that the vapour perspired passes through leather, even when prepared so as to keep out moisture, at least for a certain time. It is possible, then, that water, when in the state of vapour, or when dissolved in air, may be absorbed, although water, while in the state of water, may be incapable of pervading the cuticle. The experiments, therefore, which have hitherto been made upon the absorption of the skin, are insufficient to prove that air and vapour cannot pervade the cuticle, provided there are any facts to render the contrary supposition probable.

Now that there are such facts, cannot be denied. We shall not indeed produce the experiment of Van Mons as a fact of that kind, because it is liable to objections, and at best is very indecisive. Having a patient under his care who, from a wound in the throat, was incapable for several days of taking any nourishment, he kept him alive during that time, by applying to the skin in different parts of the body, several times a day, a sponge dipt in wine or strong soup. A fact mentioned by Dr. Watson is much more important, and much more decisive. A lad at Newmarket, who had been almost starved in order to bring him down to such a weight as would qualify him for running a horse-race, was weighed in the morning of the race-day; he was weighed again an hour after, and was found to have gained 30 ounces of weight; yet in the interval he had only taken half a glass of wine. Here absorption must have taken place, either by the skin, or lungs, or both. The difficulties in either case are the same; and whatever renders absorption by one probable, will equally strengthen the probability that absorption takes place by the other. See Physiology.

PERULA, a genus of the class and order dioecia polyandria. There is one species, a tree of New Grenada.

PETAL, among botanists, an appellation given to the flower-leaves, in opposition to the folia, or common leaves of the plant. See Botany.

PETALOMA, a genus of the decandria monogynia class and order: the calyx is goblet-shaped, five-toothed; petals five; stamina on margin of calyx; berry one-celled, seeds one or four. There are two species, trees of Jamaica and Guiana.

PETARD, in the art of war, a metalline engine, somewhat resembling a high-crowned hat. The petard may be considered as a piece of ordnance; it is made of copper mixed with brass, or of lead with tin: its charge is from five to six pounds of powder, which reaches to within three fingers'-breadth of the mouth; the vacancy is filled with tow, and stopped with a wooden tompion, the mouth being strongly bound up with cloth tied very tight with ropes. It is covered up with a madrier, or wooden plank, that has a cavity to receive the mouth of the petard, and fastened down with ropes.

Its use is in a clandestine attack to break down gates, bridges, barriers, &c. to which it is hung; and this it does by means of the wooden plank. It is also used in countermines to break through the enemy's galleries, and give their mines vent. The invention of petards is ascribed to the French Huguenots, in 1579, who with them took Cahors, as d'Aubigné tells us.

PETECHIÆ. See Medicine.

PETER-PENCE, an antient tax of a penny on each house, paid to the pope. It was called Peter-pence, because collected on the day of St. Peter ad vincula, and sent to Rome; whence it was also called Rome-scot, and Rome-penny.

PETESIA, a genus of the tetrandria monogynia class and order: the corolla is one-petalled, funnel-form, stigma bifid, berry many-seeded. There are three species, shrubs of South America and the West Indies.

PETIOLE, in botany, the slender stalk that supports the leaves of a plant.

PETTIA, a genus of the class and order tetrandria monogynia: the calyx is four-toothed, inferior; corolla four-parted, drupe with a two-celled nut. There is one species, a small tree of St. Domingo.

PETITIO PRINCIPII, in logic, the taking a thing for true, and drawing conclusions from it as such, when it is really false, or at least wants to be proved, before any inferences can be deduced from it.

PETITION. No petition to the king, or to either house of parliament, for any alteration in church or state, shall be signed by above twenty persons, unless the matter thereof is approved by three justices of the peace, or the major part of the grand jury in the country; and in London by the lord mayor, aldermen, and common council: nor shall any petition be presented by more than ten persons at a time.

PETITION IN CHANCERY, a request in writing, directed to the lord chancellor or master of the rolls, shewing some matter or cause, whereupon the petitioner prays somewhat to be granted him.

PETIVERIA, a genus of the tetragynia order, in the hexandria class of plants, and in the natural method ranking under the 12th order, holoraceæ. The calyx is tetraphyllous; there is no corolla; and but one seed, with reflexed awns at the top. There are two species (Guinea hen-weed), herbs of the West Indies.

PETREA, in botany, a genus of the didynamia angiosperima class of plants, with a monopetalous flower, divided into five rounded segments at the limb. There is one species, a shrub of South America.

PETRIFACTION, in natural history, denotes the conversion of wood, bones, and other substances, principally animal or vegetable, into stone. These bodies are more or less altered from their original state, according to the different substances they have lain buried among in the earth; some of them having suffered very little change, and others being so highly impregnated with crystalline, sparry, pyritical, or other extraneous matter, as to appear mere masses of stone, or lumps of the matter of the common pyrites; but they are generally of the external dimensions, and retain more or less of the internal figure, of the bodies into the pores of which this matter has made its way. The animal substances thus found petrified are chiefly sea-shells; the teeth, bony palates, and bones of fish; the bones of land-animals, &c. These are found variously altered, by the insinuation of stony and mineral matter into their pores; and the substance of some of them is found to be wholly gone, there being only stony, sparry, or other remaining matter deposited in the shape and form of the original matter, which has gradually wasted away, and these may be regarded as the true petrifactions.

Respecting the manner in which petrifaction is accomplished, we know but little. It has been thought by many philosophers, that this was one of the rare processes of nature; and accordingly such places as have afforded a view of it, have been looked upon as great curiosities. However, it is now discovered, that petrifaction is exceedingly common; and that every kind of water carries with it some earthy particles, which being precipitated from it, become stone of a greater or lesser degree of hardness; and this quality is most remarkable in those waters which are much impregnated with selenetic matter. Of late, it has also been found by some observations on a petrifaction in East Lothian in Scotland, that iron contributes greatly to the process: and this it may do by its precipitation of any aluminous earth which happens to be dissolved in the water by means of an acid; for iron has the property of precipitating this earth, though it cannot precipitate the calcareous kind. The calcareous kinds of earth, however, by being soluble in water without any acid, must contribute very much to the process of petrifaction, as they are capable of a great degree of hardness by means only of being joined with carbonic acid, on which depends the solidity of our common cement or mortar used in building houses.

The name petrifaction belongs only, as we have seen, to bodies of vegetable or animal origin; and in order to determine their class and genus, or even species, it is necessary that their texture, their primitive form, and in some measure their organization, are still discernible. Thus we ought not to place the stony kernels moulded in the cavity of some shell, or other organized body, in the rank of petrifactions properly so called.

Petrifactions of the vegetable kingdom are almost all either gravelly or siliceous; and are found in gulleys, trenches, &c. Those which strike fire with steel are principally found in sandy fissures; those which effervesce in acids are generally of animal origin, and are found in the horizontal beds of calcareous earth, and sometimes in beds of clay or gravel; in which case the nature of the petrifaction is different. As to the substances which are found in gypsum, they seldom undergo any alteration, either with respect to figure or composition, and they are very rare.

A petrified substance, strictly speaking, is nothing more than the skeleton, or perhaps image, of a body which has once had life, either animal or vegetable, combined with some mineral. Thus petrified wood is no longer wood, properly speaking. When wood is buried in certain places, lapidific fluids, extremely divided and sometimes coloured, insinuate themselves into its pores, and fill them up. These fluids are afterwards moulded and condensed. The solid part of the wood is decomposed and reduced into powder, which is expelled without the mass by aqueous filtrations. In this manner, the places which were formerly occupied by the wood are now left empty in the form of pores. This operation of nature produces no apparent difference either of the size or of the shape; but it occasions, both at the surface and in the inside, a change of substance, and the ligneous texture is inverted; that is to say, that which was pore in the natural wood, becomes solid in that which is petrified; and that which was solid or full in the first state, becomes porous in the second. In this way, says M. Musard, petrified wood is much less extended in pores than solid parts, and at the same time forms a body much more dense and heavy than the first. As the pores communicate from the circumference to the centre, the petrifaction ought to begin at the centre, and end with the circumference of the organic body subjected to the action of the lapidific fluids.

In proportion to the tenderness and bad quality of wood, it imbibes the greater quantity of water; therefore this sort will unquestionably petrify more easily than that which is hard. It is thought that all the petrified wood so often found in Hungary, has been originally soft, such as firs or poplars. Suppose a piece of wood buried in the earth; if it is very dry, it will suck up the moisture which surrounds it like a spunge. This moisture, by penetrating it, will dilate all the parts of which it is composed. The trachiæ, or air-vessels, will be filled first; and then the lymphatic vessels, and those which contain the succus proprius, as they are likewise empty. The water which forms this moisture keeps in solution a greater or a less quantity of earth; and this earth, detached, and carried along in its course, is reduced to such an attenuated state, that it escapes our eyes, and keeps itself suspended, whether by the medium of fixed air or by the motion of the water. Such is the lapidific fluid. Upon evaporation, or the departure of the menstruum, this earth, sand, or metal, again appears in the form of precipitate or sediment in the cavities of the vessels, which by degrees are filled with it. This earth is there moulded with exactness: the lapse of time, the simultaneous and partial attraction of the particles, make them adhere to one another; the lateral suction of the surrounding fibres, the obstruction of the moulds, and the hardening of the moulded earth, become general; and there consists nothing but an earthy substance which prevents the sinking of the neighbouring parts. If the deposit is formed of a matter in general pretty pure, it preserves a whiter and clearer colour than the rest of the wood; and as the concentric layers are only perceptible and distinct in the wood, because the vessels are there more apparent on account of their size, the little earthy cylinders, in the state of petrified wood, must be there a little larger, and consequently must represent exactly the turnings and separations of these layers. At the place of the utriculi, globules are observed, of which the shapes are as various as the moulds wherein they are formed. The anastomoses of the proper and lymphatic vessels form, besides, points of support or reunion for this stony substance.

With regard to holes formed by worms in any bits of wood, before they had been buried in the earth, the lapidific fluid, in penetrating these great cavities, deposits there as easily the earthy sediment, which is exactly moulded in them. These vermiform cylinders are somewhat less in bulk than the holes in which they are found, which is owing to the retreat of the more refined earth, and to its drying up.

Let any one represent to himself this collection of little cylinders, vertical, horizontal, inclined in different directions, the stony masses of utriculi and of anastomoses, and he will have an idea of the stony substance which forms the ground-work of petrifaction. Hitherto not a single ligneous part is destroyed; they are all existing, but surrounded on every side with earthy deposits; and that body which, during life, was composed of solid and of empty parts, is now entirely solid: its destruction and decomposition do not take place till after the formation of these little deposits. In proportion as the water abandons them, it penetrates the ligneous substance, and destroys it insensibly. The woody fibres being decomposed, form in their turn voids and interstices, and there remains in the whole piece nothing but little stony cylinders. But in proportion as these woody fibres disappear, the surrounding moisture, loaded with earth in the state of dissolution, does not fail to penetrate the piece of wood, and to remain in its new cavities. The new deposit assumes exactly the form of decomposed fibres; it envelops in its turn the little cylinders which were formed in their cavities, and ends by incorporating with them. We may suppose here, that in proportion as it decomposes, there is a reaction of the ligneous part against the lapidific fluid: from this reaction a colour arises which stains more or less the new deposit; and this colour will make it easily distinguishable from that which has been laid in the inside of the vessels. In all petrified wood this shade is generally perceptible.

We have then, says M. Mongez, four distinct epochs in the process by which nature converts a piece of wood into stone, or, to speak more justly, by which she substitutes a stony deposit in its place: 1. Perfect vegetable wood, that is to say, wood composed of solid and of empty parts, of ligneous fibres, and of vessels 2. Wood having its vessels obstructed and choked up by an earthy deposit, while its solid parts remain unaltered. 3. The solid parts attacked and decomposed, forming new cavities betwixt the stony cylinders, which remain in the same state, and which support the whole mass. 4. These new cavities filled with new deposits, which incorporate with the cylinders, and compose nothing else but one general earthy mass, representing exactly the piece of wood.

Among the petrifactions of vegetables called dendrolites, are found parts of shrubs, stems, roots, portions of the trunk, some fruits, &c. We must not, however, confound the impressions of mosses, ferns, and leaves, nor incrustrations, with petrifactions.

Among the petrifactions of animals, we find shells, crustaceous animals, polyparii, some worms, the bony parts of fishes and of amphibious animals, few or no real insects, rarely birds and quadrupeds, together with the bony portions of the human body. The cornua ammonis are petrified serpents; and with regard to figured and accidental bodies, these are lusus naturæ.

In order, says M. Bertrand, in his Dictionnaire des Fossiles, that a body should become petrified, it is necessary that it is, 1. Capable of preservation under ground. 2. That it is sheltered from the air and running water (the ruins of Herculaneum prove that bodies which have no connection with free air preserve themselves untouched and entire). 3. That it is secured from corrosive exhalations. 4. That it is in a place where there are vapours or liquids, loaded eithher with metallic or stony particles in a state of dissolution, and which, without destroying the body, penetrate it, impregnate it, and unite with it in proportion as its parts are dissipated by evaporation.

It is a question of great importance among naturalists, to know the time which nature employs in petrifying bodies of an ordinary size. It was the wish of the late emperor, duke of Lorraine, that some means should be taken for determining this question. M. le chevalier de Baillu, director of the cabinet of natural history of his imperial majesty, and some other naturalists, had, several years before, the idea of making a research which might throw some light upon it. His imperial majesty being informed by the unanimous observations of modern historians and geographers, that certain pillars which are actually seen in the Danube in Gervia, near Belgrade, are remains of the bridge which Trajan constructed over that river, presumed that these pillars having been preserved for so many ages must be petrified, and that they would furnish some information with regard to the time which nature employs in changing wood into stone. The emperor thinking this hope well founded, and wishing to satisfy his curiosity, ordered his ambassador at the court of Constantinople to ask permission to take up from the Danube one of the pillars of Trajan's bridge. The petition was granted, and one of the pillars was accordingly taken up; from which it appeared that the petrifaction had only advanced three-fourths of an inch in the space of 1500 years. There are, however, certain waters in which the transmutation is more readily accomplished. Petrifactions appear to be formed more slowly in earths that are porous and in a slight degree moist than in water itself.

When the foundations of the city of Quebec in Canada were dug up, a petrified savage was found among the last beds to which they proceeded. Although there was no idea of the time at which this man had been buried under the ruins, it is however true, that his quiver and arrows were still well preserved. In digging a lead-mine in Derbyshire in 1744, a human skeleton was found among stags' horns. It is impossible to say how many ages this carcase had lain there. In 1695 the entire skeleton of an elephant was dug up near Tonna, in Thuringia. Some time before this epoch the petrified skeleton of a crocodile was found in the mines of that country. We might cite another fact equally curious which happened at the beginning of the last century. John Munte, curate of Slægarp in Scania, and several of his parishioners, wishing to procure turf from a drained marshy soil, found, some feet below ground, an entire cart with the skeletons of the horses and carter. It is presumed that there had formerly been a lake in that place, and that the carter attempting to pass over on the ice, had by that means probably perished. In fine, wood partly fossil, and partly coaly, has been found at a great depth, in the clay of which tile was made for the abbey of Fontenay. It is but very lately that fossil wood was discovered at the depth of 75 feet in a well betwixt Issi and Vauvres, near Paris. This wood was in sand betwixt a bed of clay and pyrites, and water was found four feet lower than the pyrites. M. de Laumont, inspector-general of the mines, says that in the lead-mine at Pontpéan, near Rennes, is a fissure, perhaps the only one of its kind. In that fissure, sea-shells, rounded pebbles, and an entire beech, have been found 240 feet deep. This beech was laid horizontally in the direction of the fissure. Its bark was converted into pyrites, the sap-wood into jet, and the centre into coal.

A great many pieces of petrified wood are found in different counties of France and Savoy. In Cobourg in Saxony, and in the mountains of Misnia, trees of a considerable thickness have been taken from the earth, which were entirely changed into a very fine agate, as also their branches and their roots. In sawing them, the annual circles of their growth have been distinguished. Pieces have been taken up, on which it was distinctly seen that they had been gnawed by worms; others bear visible marks of the hatchet. In fine, pieces have been found which were petrified at one end, while the other still remained in the state of wood fit for being burned. It appears then that petrified wood is a great deal less rare in nature than is commonly imagined.

Mr. Kirwan observes on the subject of petrifications, 1. Those of shells are found on or near the surface of the earth; those of fish deeper; and those of wood deeper still. Shells in substance are found in vast quantities, and at considerable depths. 2. The substances most susceptible of petrifaction are those which most resist the putrefactive process; of which kind are shells, the harder kinds of wood, &c.; while the softer parts of animals, which easily putrefy, are seldom met with in a petrified state. 3. They are most commonly found in strata of marl, chalk, limestone, or clay; seldom in sandstone, still more seldom in gypsum; and never in gneiss, granite, basaltes, or schoerl. Sometimes they are found in pyrites, and ores of iron, copper, and silver; consisting almost always of that kind of earth or other mineral which surrounds them; sometimes of silex, agate, or carnelian. 4. They are found in climates where the animals themselves could not have existed. 5. Those found in slate or clay are compressed and flattened.

The different species of petrifactions, according to Cronstedt, are,

I. Terræ larvatæ; extraneous bodies changed into a limy substance, or calcareous changes. These are, 1. Loose or friable. 2. Indurated. The former are of a chalky nature, in form of vegetables or animals; the second filled with solid limestone in the same forms. Some are found entirely changed into a calcareous spar.

On these petrifactions Cronstedt observes, that shells and corals are composed of limy matter even when still inhabited by their animals, but they are classed among the petrifactions as soon as the calcareous particles have obtained a new arrangement: for example, when they have become sparry, filled with calcareous earth either hardened or loose, or when they lie in the strata of the earth. "These (says he) form the greatest part of the fossil collections which are so industriously made, often without any regard to the principal and only use they can be of, viz. that of enriching zoology. Mineralogists are satisfied with seeing the possibility of the changes the limestone undergoes in regard to its particles; and also with receiving some insight into the alteration which the earth has been subject to from the state of the strata which are now found in it." The calcined shells, where the petrifactions are of a limy or chalky nature, answer extremely well as a manure; but the indurated kind serve only for making grottoes. Gypseous petrifactions are extremely rare: however, Chardin informs us that he had seen a lizard inclosed in a stone of that kind in Persia.

II. Larvæ, or bodies changed into a flinty substance. These are all indurated, and are of the following species: 1. Carnelians in form of shells from the river Tomm in Siberia. 2. Agate in form of wood; a piece of which is said to be in the collection of the count de Tessin. 3. Coralloids of white flint (millepora) found in Sweden. 4. Wood of yellow flint found in Italy, in Turkey near Adrianople, and produced by the waters of Lough-neah in Ireland.

III. Larvæ argillaceæ; where the bodies appear to be changed into clay. These are found either loose and friable, or indurated. Of the former kind is a piece of porcelain clay met with in a certain collection, with all the marks of the root of a tree upon it. Of the latter kind is the osteocolla; which is said to be the roots of the poplar-tree changed, and not to consist of any calcareous substance. A sort of fossil ivory, with all the properties of clay, is said likewise to be found in some places.

IV. Larvæ insalitæ; where the substances are impregnated with great quantities of salts. Human bodies have been twice found impregnated with vitriol of iron in the mine of Fahlun, in the province of Dalarne in Sweden. One of them was kept for several years in a glass-case, but at last began to moulder and fall to pieces. Turf and roots of trees are likewise found in water strongly impregnated with vitriol. They do not flame, but look like a coal in a strong fire; neither do they decay in the air.

V. Bodies penetrated by mineral inflammable substances. 1. By pit-coal, such as wood; whence some have imagined coal to have been originally produced from wood. Some of these substances are fully saturated with the coaly matter; others not. Among the former Cronstedt reckons jet; among the latter the substance called mumia vegetablis; which is of a loose texture, resembling amber, and may be used as such. 2. Those penetrated by asphaltum or rock-oil. The only example of these given by our author is a kind of turf in the province of Skone in Sweden. The Egyptian mummies, he observes, cannot have any place among this species, as they are impregnated artificially with asphaltum, in a manner similar to what happens naturally with the wood and coaly matter in the last species. 3. Those impregnated with sulphur which has dissolved iron, or with pyrites. Human bodies, bivalve and univalve shells, and insects, have been all found in this state; and the last are found in the alum state at Andrarum, in the province of Skone in Sweden.

VI. Larvæ metalliferæ; where the bodies are impregnated with metals. These are, 1. Covered with native silver; which is found on the surface of shells in England. 2. Where the metal is mineralised with copper and sulphur. Of this kind is the fahlertz or grey silver-ore, in the shape of ears of corn, and supposed to be vegetables, found in argillaceous slate at Frankenberg and Tahlitteren in Hesse. 3. Larvæ cupriferæ, where the bodies are impregnated with copper. To this species principally belong the turquoise or Turkey stones, improperly so called; being ivory and bones of the elephant, or other animals, impregnated with copper. At Simore in Languedoc there are bones of animals dug up, which, during calcination, assume a blue colour; but according to Cronstedt, it is not probable that these owe their colour to copper. 3. With mineralised copper. Of these our author gives two examples. One is, where the copper is mineralised with sulphur and iron, forming a yellow marcasitical ore. With this some shells are impregnated, which lie upon a bed of loadstone in Norway. Other petrifactions of this kind are found in the form of fish in different parts of Germany. The other kind is where the copper is impregnated with sulphur and silver. Of this kind is the grey silver-ore, like ears of corn, found in the slate-quarries at Hesse. 4. Larvæ ferriferæ, with iron in form of a calx, which has assumed the place or shape of extraneous bodies. These are either loose or indurated. Of the loose kind are some roots of trees found at the lake Langelma in Finland. The indurated kinds are even exemplified in some wood found at Orbissan in Bohemia. 5. Where the iron is mineralised, as in the pyritaceous larvæ already described.

VII. Where the bodies are tending to decomposition, or in a way of destruction. Among these, our author enumerates mould and turf, &c.

PETROCARYA, a genus of the class and order heptandria monogynia. The calyx is five-cleft, turbinate; corolla five-petalled; filaments twenty-four; drupe inclining, and two-celled nut. There are two species, trees of Guiana.

PETROLEUM. See Bitumen.

PETROMYZON, the *lamprey*, a genus of fishes belonging to the class of amphibia nantes. It has seven spiracula at the side of the neck, no gills, a fistula on the top of the head, and no breast or belly fins. There are eight species, distinguished by peculiarities in their back fins.

1. The marinus, or sea-lamprey, is sometimes found so large as to weigh four or five pounds. It greatly resembles the eel in shape, but its body is larger, and its snout longer, narrower, and sharper at the termination. The opening of the throat is very wide; each jaw is furnished with a single row of very small teeth; in the middle of the palate are situated one or two other teeth, which are longer, stronger, and moveable towards the inside of the throat.

The lamprey is an inhabitant of the ocean, ascending rivers chiefly during the latter part of winter and the early months of spring; and after a residence of a few months in fresh water, again returning to the sea: it is viviparous, and the young are observed to be of slow growth; contrary to the assertions of some writers, who have supposed the lamprey to be a short-lived fish. When in motion this fish is observed to swim with considerable vigour and rapidity, but it is more commonly seen attached by the mouth to some large stone or other substance, the body hanging at rest, or obeying the motion of the current: so strong is the power of adhesion exerted by this animal, that a stone of the weight of more than twelve pounds may be raised without forcing the fish to forego its hold. The general habits of the lamprey seem pretty much to resemble those of the eel, and it is supposed to live principally on worms and young fish. Like the eel it is remarkably tenacious of life; the several parts, when cut in pieces, will long continue to move; and the head will strongly attach itself for several hours to a stone, though by far the greater part of the body is cut away from it.

Among the cartilaginous fishes none is so destitute of all appearance of real bone as the lamprey, in which the spine itself is no other than a mere soft cartilage, without any processes or protuberances whatsoever. Among other particulars in its anatomy, it is remarkable that the heart, instead of being inclosed in a soft pericardium, as in other animals, is guarded by a strong cartilaginous one: the liver, which is of an oblong form, is of a fine grass-green colour, somewhat deeper in the female fish, and may be used for the purpose of a pigment.

A vulgar error, arising from inattentive inspection, and total ignorance of the nature of the animal, is said sometimes to prevail, viz. that the lamprey is furnished with nine eyes on each side; this mistake appears to have excited unusual indignation in sir T. Brown.

As an article of food, the lamprey has for many ages maintained its credit as an exquisite dainty; and has uniformly made its appearance at the most splendid of our antient entertainments. The death of king Henry the First, it is well known, is attributed to a too luxurious indulgence in this his favorite dish. It still continues to be in high esteem; and we are told by Mr. Pennant that the city of Gloucester continues to send yearly, at Christmas, a present of a rich lamprey-pie to the king. It sometimes happens that lampreys at that season are so rare that a guinea is demanded for the price of a single fish. They are most in season during March, April, and May, and are observed to be much more firm when fresh-arrived from sea than when they have been a considerable time in fresh water. They are found in several of the British rivers, but that which is most celebrated for them is the Severn. In the mouths of some of the larger European rivers they are sometimes taken in such quantities that it is impossible to use them in their fresh state; they are therefore grilled and moderately salted, and afterwards barrelled up for sale, with the addition of vinegar and spices.

2. Petromyzon fluviatilis, lampern. This species is, according to Dr. Bloch, an inhabitant of the sea, and ascends in spring-time most of the European rivers, in which it is found much more frequently and plentifully than the great lamprey. With us it is found in great quantities in the Thames, the Severn, and the Dee. It is often potted with the larger lamprey, and is by some preferred to it, as being milder-tasted. Mr. Pennant informs us that vast quantities are taken about Mortlake, and sold to the Dutch, as baits for their cod and turbot fisheries. According to this author above four hundred and fifty thousand have been sold in a season, at forty shillings per thousand, and about a hundred thousand have been occasionally sent to Harwich for the same purpose. The Dutch, it is added, have the secret of preserving them till the time of the turbot-fishery. Great quantities, says Dr. Bloch, are taken in the march of Brandenburgh, and in Pomerania, Silesia, and Prussia; and after frying, are

packed in barrels by layers, between each of which is a layer of bay-leaves, and spices, sprinkled over with vinegar. In this state they are sent into many other parts of the German empire. In the river Bauster in Courland, great quantities are taken from beneath the ice with nets; they are much larger than those found elsewhere, and are packed in snow, and sent to any distance; and when put into cold water recover themselves. This species spawns in March and April, and is a prolific fish. It is so tenacious of life, that it will live many days out of water.

3. Petromyzon planeri, Planer's lamprey: length from five or six to ten inches; general resemblance that of the lampern: native of the rivers of Thuringia and other parts of the German empire. Like most of the genus, tenacious of life, living for the space of a quarter of an hour when immersed in spirits of wine, and moving with violence during the whole time. When thus killed in spirits, the mouth remains open, but when the fish dies in water it is shut.

4. Petromyzon branchialis, minute lamprey: inhabits the European rivers; in England more frequent in the Isis than elsewhere. Instead of concealing itself under stones, this species lodges itself among the mud, and is not observed to adhere to any other body like the rest of the genus: it is used as a bait for other fish. It seems to have been first distinctly described as an English species by Dr. Plot, in his History of Oxfordshire.

5. Petromyzon sanguisuga, leech lamprey. It seems in many points so nearly to resemble the common lamprey as to leave some suspicion of its being the young of that species; yet Mons. Noel seems convinced of its being specifically different. It is said to be found only at those times in which the shad (clupea alosa) is in the river. These fishes it persecutes, by fastening beneath their bellies, and sucking their blood with the avidity of a leech: its body being constantly found full of that fluid alone: they sometimes attack salmon in a similar way, but from the greater thickness of the skin in those fishes, are able to obtain but a small quantity of blood from them.

PETUNSE, in natural history, one of the two substances whereof the porcelain or China-ware is made. The petunse is a coarse kind of flint or pebble, the surface of which is not so smooth when broken as that of our common flint. See STONEWARE.

PEUCEDANUM, or SULPHURWORT, a genus of the digynia order, in the pentandria class of plants, and in the natural method ranking under the 45th order, umbellatæ. The fruit is lobated, striated on both sides, and surrounded by a membrane; the involucra are very short. There are 10 species, none of which have any remarkable properties excepting the officinale, or common hog's-fennel, growing naturally in the English salt marshes. The roots, when bruised, have a strong fetid scent like sulphur, and an acrid, bitterish, unctuous taste. Wounded in the spring they yield a considerable quantity of yellow juice, which dries into a gummy resin, and retains the strong smell of the root. The expressed juice was used by the antients in lethargic disorders.

PEWTER, a factitious metal, used in making domestic utensils, as plates, dishes, &c. See ZINC.

PEZIZA, cup-mushroom, a genus of the natural order of fungi, in the cryptogamia class of plants. The fungus is campanulated and sessile. Linnæus enumerates 11 species; Dr. Withering, 40 British species.

PHACA, a genus of the decandria order, in the diadelphia class of plants; and in the natural method ranking under the 32d order, papilionaceæ. The legumen is semibilocular. There are 11 species.

PHÆTHUSA, a genus of the class and order syngenesia polygamia superflua. The calyx is subcylindric, many-leaved; florets hermaphrodite; recept. chaffy; seeds vispid. There is one species, a tree of Virginia.

PHAETON, in ornithology, a genus of birds belonging to the order of anseres, the characters of which are: The bill is sharp, straight, and pointed; the nostrils are oblong, and the hinder toe is turned forward. There are two species, viz.

1. The demersus, or red-footed pinguin, has a thick, arched, red bill; the head, hind-part of the neck, and the back, of a dusky purplish hue, and breast and belly white; brown wings, with the tips of the feathers white; instead of a tail, a few black bristles; and red legs. It is found on Pinguin isle, near the Cape of Good Hope, is common all over the South Seas, and is about the size of a goose.

2. The ethereus, or tropic bird, is about the size of a partridge, and has very long wings. The bill is red, with an angle under the lower mandible. The eyes are encompassed with black, which ends in a point towards the back of the head. Three or four of the larger quill-feathers towards their ends are black, tipped with white; all the rest of the bird is white, except the back, which is variegated with curved lines of black. The legs and feet are of a vermilion red. The toes are webbed. The tail consists of two long straight narrow feathers, almost of equal breadth from their quills to their points.

The name tropic bird, given to this genus, arises from its being chiefly found within the tropical circles; but we are not to conclude that they never stray voluntarily, or are driven beyond them: for we have met with a few instances to prove the contrary. It is, however, so generally found within the tropical limits, that the sight of this bird alone is sufficient to inform the mariner of a very near approach to, if not his entrance therein. It has also been thought to portend the contiguity of land; but this has often proved fallacious, as it is not unfrequently found at very great distances from it. The flight of this bird is often to a prodigious height; but at other times it is seen along with the frigate-pelican, booby, and other birds, attending the flying-fishes at their rise from the water, driven from their native element into the air by their watery enemies, the shark, porpoise, albicore, bonito, and dolphin, which pursue them beneath, and prey upon them. These birds are sometimes observed to rest on the surface of the water, and have been now and then seen in calm weather upon the backs of the drowsy tortoises, supinely floating in the sea, so that they have been easily taken by the long-boat manned. On shore they will perch on trees, and are said to breed in the woods, on the ground beneath them. They have been met with in plenty on the islands of St. Helena, Ascension, Mauritius, New Holland, and various places in the South Seas; but in no place so numerous as at Palmerston island, where these birds, as well as the frigates, were in such plenty, that the trees were absolutely loaded with them, and so tame, that they suffered themselves to be taken off the boughs with the hand. At Otaheite, and in the Friendly isles, the natives give them the names of baingoo and toolaiee. Some ornithologists reckon two other species (perhaps varieties) of the tropic bird.

PHALÆNA, *moth*, a genus of insects of the order lepidoptera: the generic character is; antennæ setaceous, gradually lessening from base to tip; wings (when sitting) generally deflex (flight nocturnal). This genus, like that of papilio, containing a vast number of species, is divided into assortments, according to the different habits of the animals. These assortments are as follow, viz.

Attaci, or those in which the wings, when at rest, are spread out horizontally.

Bombyces, in which the wings are incumbent, and the antennæ pectinated.

Noctuæ, with incumbent wings and setaceous antennæ.

Geometræ, with wings horizontally spread out, nearly as in the attaci.

Tortrices, with very obtuse wings, curved on the exterior margin.

Pyralides, with wings converging into a deltoid and slightly furcated figure.

Tineæ, with wings convoluted into a cylinder.

Alucitæ, with wings divided into distinct plumes.

These distributions, like those of the genus papilio, are not strictly accurate, and must therefore be regarded with a proper degree of allowance.

In the first division or attaci ranks the most splendid, and largest, of all the phalænæ yet known, viz. the phalæna atlas, an insect so large that the extent of its wings measures not less than eight inches and a half; the ground-colour is a very fine deep orange-brown, and in the middle of each wing is a large subtriangular transparent spot or patch, resembling the appearance of a piece of Muscovy talc; each of these transparent parts is succeeded by a black border, and across all the wings run lighter and darker bars, exhibiting a very fine assortment of varying shades; the upper wings are slightly curved downwards at their tips in a falcated manner, and the lower wings are edged with a border of black spots on a pale buff-coloured ground; the antennæ are widely pectinated with a quadruple series of fibres, exhibiting a highly elegant appearance. This insect is a native of both the Indies, and occasionally varies both in size and colours.

Phalæna luna is an American species, of large size, and extremely beautiful; its colour is a most elegant pea-green, with a small yellowish eye-shaped spot with a transparent centre in the middle of each wing, and the lower wings are produced at the bottom into a long and broad tail or continuation: the ridge of the upper wings is broad, and of a fine purple-brown colour; the head and thorax yellowish white, and the body milk-white.

Of the European species of this division beyond comparison the finest is the phalæna junonia (ph. pavonia Lin.), a native of many parts of Germany, Italy, France, &c. but not yet observed in England. It measures about six inches in extent of wings, and is varied by a most beautiful assortment of the most sober colours, consisting of different shades of deep and light grey, black, brown, &c. On the middle of each wing is an eye-shaped spot, having the disk black, shaded on one side with blue, surrounded with red-brown, and the whole included by a circle of black. Lastly, all the wings are bordered by a deep edging of very pale brown, with a whiter line immediately adjoining to the darker part of the wing: the antennæ are finely pectinated. The caterpillar, which feeds on the apple, pear, &c. is hardly less beautiful than the insect itself: it is of a fine apple or yellowish-green colour, with each segment of the body ornamented by a row of upright prominences of a bright blue colour, with black radiated edges, and surrounded by long black filaments, each of which terminates in a clavated tip. This larva, when ready for its change, envelops itself in an oval web with a pointed extremity, and transforms itself into a large short chrysalis, out of which afterwards emerges the moth.

The phalæna pavonia minor, or smaller peacock-moth, is a native of England, and is commonly called the emperor moth. In every respect, except size, it so greatly resembles the former, that Linnæus chose to consider it as a permanent variety only of the same species. The larva and pupa are also of the same appearance with those of the preceding, but on a much smaller scale.

The bombyces constitute a very numerous tribe, of which the phalæna caja or great tiger-moth may serve as an example. This species is one of the larger English moths, and is of a fine pale cream-colour, with chocolate-brown bars and spots; the lower wings red, and black spots; the thorax chocolate-brown, with a red collar round the neck; and the body red, with black bars. The caterpillar is of a deep brown, with white specks; extremely hairy, and feeds on various plants. It changes into a chrysalis in June, and the fly appears in July.

Phalæna fuscicauda or the brown-tail moth is remarkable for the ravages which its caterpillar commits, by destroying the foliage of trees and hedges, and reducing them to a perfectly bare appearance. The moth itself is about a third part less than that of a silkworm, and is of a fine satiny white, except the hinder part of the body, which is of a deep brown. The caterpillar is brown, with ferruginous hairs, a row of white spots along each side, and two red spots on the lower part of the back: it is of a gregarious nature, vast numbers residing together under one common web: they are hatched early in autumn, from eggs laid by the parent moths, and immediately form for themselves a small web, and begin feeding on the foliage of the tree or shrub on which they were placed: they marshal themselves with great regularity for this purpose in rows, and at first devour only the upper pellicle and the green parenchyma of the leaves, and in the evening retire to their web. In about three weeks they cast their skin, and afterwards proceed to feed as before, enlarging their web from time to time, and forming it on all sides as strong and secure as possible. In this they remain the whole winter in a state of torpidity, till being enlivened by the warmth of the returning spring, they again issue from their covering, and being now grown stronger, begin to devour the whole substance of the leaves, instead of contenting themselves with the upper part as in their very young state. The destruction which they sometimes cause to the verdure of the country may be judged of by their ravages in the year 1782, when, according to the account of the ingenious Mr. Curtis, author of the Flora Londinensis, &c. in many parishes about London subscriptions were opened, and the poor people employed, to cut off and collect the webs at one shilling per bushel, which were burned, under the inspection of the church-wardens, overseers, or beadles, of the respective parishes. At the first onset of this business, Mr. Curtis assures us, he was informed that fourscore bushels were collected in one day in the parish of Clapham alone. When these caterpillars are arrived at full growth, which is usually about the beginning of June, each spins itself a separate web, in which it changes to a dark-brown chrysalis, out of which in the beginning of July proceeds the moth. The ravages of these insects in the current year, 1806, have been scarcely less than those above recorded.

But of all the moths of the tribe bombyx the phalæna mori, or silkworm moth, is by far the most important. This is a whitish moth, with a broad pale-brown bar across each of the upper wings. The caterpillar or larva, emphatically known by the title of the silkworm, is, when full grown, nearly three inches long, and of a yellowish-grey colour; on the upper part of the last joint of the body is a horn-like process, as in many of the sphinges. It feeds, as every one knows, on the leaves of the white mulberry, in defect of which may be substituted the black mulberry, and even, in some instances, the lettuce and a few other plants. The silkworm remains in its larva state about six weeks, changing its skin four times during that period, and, like other caterpillars, abstaining from food for some time before each change. When full-grown, the animal entirely ceases to feed, and begins to form itself a loose envelopement of silken fibres in some convenient spot which it has chosen for that purpose; and afterwards proceeds to enwrap itself in a much closer covering, forming an oval yellow silken case or ball, about the size of a pigeon's egg, in which it changes to a chrysalis, and after lying thus inclosed for the space of about fifteen days, gives birth to the moth. This however is always carefully prevented when the animals are reared for the purpose of commerce, the moth greatly injuring the silk of the ball by discharging a quantity of coloured fluid before it leaves the cell: the silk-balls are therefore exposed to such a degree of heat, as to kill the inclosed chrysalides, a few only being saved for the breed of the following year. The moth, when hatched, is a very short-lived animal, breeding soon after its exclusion; and when the females have laid their eggs, they, as well as the males, survive but a very short time.

The length of the silken fibre or thread drawn by the silkworm may be supposed to differ considerably in different silk-balls. According to Boyle, as quoted by Derham, a lady, on making the experiment, found the length of the ball to be considerably more than 300 yards, though the weight was only two grains and a half. The abbé La Pluche informs us, that of two balls one measured 924 feet, and the other 930. It may be proper to add, that the silk throughout its whole length is double, or composed of two conjoined or agglutinated filaments. See SILK MANUFACTURE.

In the next divison, or noctuæ, stands the beautiful phalæna nupta, a moderately large species, with the upper wings of a fine grey colour, elegantly clouded and varied with shades and lines of dark-brown, &c. and the under wings of a vivid crimson, with two broad transverse black bars; the body is grey, but white underneath. The caterpillar, which is of a pale flesh-coloured grey, is distinguished by a dorsal tubercle on the fore part of the body, and seeds chiefly on the willow; it changes to a chrysalis in July, and the moth appears in August and September. The division noctuæ, like that of bombyx, is extremely numerous.

As an example of the geometræ, we may adduce a very elegant moth often seen towards the middle of summer on the elder, and called phalæna sambucaria; it is moderately large, of a pale sulphur-colour, with angular wings, marked by a narrow transverse brown line or streak. It proceeds from a green caterpillar, which, like those of the rest of this section, walks in a peculiar manner, viz. by raising up the body at each progressive movement into the form of an arch or loop, the extremities nearly approaching each other. It changes in May and June into a black chrysalis, out of which in June or July proceeds the moth.

To this division also belongs that beautiful insect called the currant-bush moth, or phalæna grossulariata, so frequently seen in gardens in the month of July. It has somewhat the appearance of a butterfly, with rounded white wings, marked by numerous black spots; the upper pair being still farther decorated by a pair of deep-yellow bands: the body also is of a deep golden yellow, with black spots. The caterpillar is of similar colour, and the chrysalis black.

In the division tortrices, so named from the faculty which their caterpillars possess of rolling or twisting the leaves of the vegetables they inhabit, into a tubular form, stands the elegant phalæna prasinana, an inhabitant of the oak, and sometimes of the alder: the upper wings are of fine green, with two oblique yellow stripes; the lower wings pale or whitish. The caterpillar is of a yellowish-green, with white specks, and the end of the body orange-coloured.

In the division pyrales stands the phalæna farinalis, distinguished by the polished surface of its wings, which have a large glaucous-brown middle area or patch, while the remainder is marked by whitish streaks. This insect, when sitting, has an obtusely triangular outline, and the abdomen is turned up at the tip.

The division called tineæ, comprehends those moths which are in general of a small size, though often of very elegant colours. Of this tribe is the phalæna padella: it is of a pearly white colour, with very numerous black spots: its caterpillar is gregarious, appearing in great quantities on various sorts of fruit-trees during the decline of summer, and committing great ravages on the leaves: these caterpillars inhabit a common web, and usually move in large groupes together; their colour is a pale greyish yellow, with numerous black spots; each caterpillar, at the time of its change to chrysalis, envelops itself in a distinct oval web with pointed extremities; and many of these are stationed close to each other, hanging, in a perpendicular direction, from the internal roof of the general enclosing web; the chrysalis is blackish, and the moth appears in the month of September.

To this division also belong the moths emphatically so called, or cloth-moths. Of these the principal is the phalæna vestianella, which, in its caterpillar state, is very destructive to woollen cloths, the substance of which it devours, forming for itself a tubular case with open extremities, and generally approaching to the colour of the cloth on which it is nourished. This mischievous species changes into a chrysalis in April, and the moth, which is universally known, appears chiefly in May and June.

In the last division, called alucitæ, is one of the most elegant of the insect tribe, though not distinguished either by large size or lively colours. It is a small moth, of a snowy whiteness, and, at first view, catches the attention of the observer by the very remarkable aspect of its wings, which are divided into the most beautiful distinct plumes, two in each upper, and three in each under wing, and formed on a plan resembling that of the long wing-feathers of birds, viz. with a strong middle rib or shaft, and innumerable lateral fibres. This moth, which is the phalæna pentadactyla of Linnæus, appears chiefly in the month of August. Its caterpillar, which is yellowish-green, speckled with black, feeds on nettles, and changes into a blackish chrysalis enveloped in a white web.

Another very remarkable species of this division is the phalæna hexadactyla of Linnæus; each wing consisting of six distinct plumes. The insect is of a pale grey-brown colour, with several transverse lines or bars across the feathers, and exhibiting a very curious spectacle in the microscope. It chiefly makes its appearance in the month of September. This little moth is by the English collectors somewhat improperly called the twenty-plumed moth, the plumes being in reality twenty-four in number. See Plate Nat. Hist. figs. 325, 326, 327, 328.

PHALANGIUM, a genus of insects of the order aptera. The generic character is, legs eight; eyes two vertical, and two lateral; front furnished with cheliform antennæ; abdomen generally rounded.

Of all the insects in the order aptera, few perhaps will be found of a form more repulsive than that of the present genus; which, exclusive of its spider-like shape, is, in some species, armed with weapons resembling those of the genus aranea, but operating with greater malignity. The phalangia differ very much in size, some being very minute insects, while others are equal in magnitude to the larger kind of spiders.

The phalangium reniforme is one of the largest of the genus. This animal is a native of the hotter regions of the globe, being found in Africa and South America. It has the general appearance of a very large spider, with the thorax heart- (or rather kidney-) shaped, and the abdomen rounded: the legs are very long, and the palpi or claspers are strongly toothed on the inner side by several sharp-pointed curved processes: the first pair of legs have all the appearance of a pair of antennæ; far exceeding the rest in length, and being of a slender or filiform shape. The whole insect is of a deep chesnut-brown colour, with a yellowish cast on the abdomen. Its particular history seems to be little known, but there can be no doubt of its being of a predacious nature, living probably on the smaller insects.

Phalangium caudatum is, in general, of rather smaller size than the former, and of a lengthened shape, with shorter limbs in proportion: it is principally distinguished by the long setaceous process in which the abdomen terminates: the chelæ or claspers are large, and toothed on the inside towards the tips. The general colour of the animal is chesnut-brown. It is a native of the East Indies.

To this genus belong those well-known insects called long-legged, shepherd, or harvest spiders, being popularly considered as such, though differing very considerably from spiders properly so named. The most common insect of this kind is the phalangium opilio of Linnæus, which, during the autumn, may be observed in gardens, about walls, &c. It is remarkable for its plump, but flattish, orbicular body; and its extremely long and slender legs, which are generally so carried, that the body appears suspended or elevated to a considerable height above the surface on which the animal rests: the eyes are situated on the top of the head, and resemble two very minute glassy globules; the colour of the whole animal is a pale greyish-brown. This species preys on the smaller kind of insects in general.

Among the minute species of phalangium, the most remarkable is the phalangium cancroides of Linnæus, a very small insect, of a reddish-brown colour, and of slow motion, occasionally found among papers, dried plants, &c. &c. Its shape is obtusely oval, with a sharpened front, furnished with a pair of very long and large jointed claspers, which give the insect a very remarkable appearance; the body is very much depressed. This little insect has been occasionally referred to very different genera. It is a species which seems to vary considerably in size; those which are found in our own country rarely exceeding the length of the tenth of an inch, while in some parts of Europe it appears to arrive at twice that length. It is said by Linnæus, but probably on no just foundation, to introduce itself occasionally under the skin, and to excite a painful tumour; a circumstance which, considering the size of the animal, seems scarcely possible. It preys on smaller and weaker insects. See Plate Nat. Hist. fig. 329.

Phalangium. See Anthericum.

PHALANX, in Grecian antiquity, a square battalion, consisting of 8000 men, with their shields joined, and pikes crossing each other, so that it was next to impossible to break it.

PHALARIS, or Canary-grass, a genus of the trigynia order, in the triandria class of plants. The calyx is bivalved, carinated, and equal in length, containing the corolla. There are 12 species, of which the most remarkable are the canariensis, or manured canary-grass; and the arundinacea, or reed canary-grass. These are both natives of Britain. The first grows by the road-sides, and is frequently cultivated for the sake of the seeds, which are found to be the best food for the canary and other small birds. The second grows on the banks of rivers. It is used for thatching ricks or cottages, and endures much longer than straw. In Scandinavia they mow it twice a year, and their cattle eat it. There is a variety of this cultivated in our gardens with beautifully striped leaves. The stripes are generally green and white; but sometimes they have a purplish cast. This is commonly called painted lady-grass, ladies' tresses, or riband-grass.

PHALEUCIAN VERSE, in antient poetry, a kind of verse which consists of five feet, the first of which is a spondee, the second a dactyl, and the three last trochees: such is the following one of Martial:

1 2 3 4 5
Summam | nec metu | as di | em, nec | optes.

PHALLUS, the morel, a genus of the order of fungi, belonging to the cryptogamia class of plants. The fungus is reticulated above and smooth below. There are three species; the most remarkable are

1. The esculentus, or esculent morel, is a native of Britain, growing in woods, groves, meadows, pastures, &c. The substance, when recent, is wax-like and friable; the colour a whitish yellow, turning brownish in decay; the height of the whole fungus, about four or five inches. The stalk is thick and clumsy, somewhat tuberous at the base, and hollow in the middle. The pileus is either round or conical; at a medium about the size of an egg, often much larger; hollow within; its base united to the stalk; and its surface cellular, or latticed with irregular sinuses. The magnified seeds are oval. It is much esteemed at table both recent and dried, being commonly used as an ingredient to heighten the flavour of ragouts. We are informed by Gleditsch, that morels are observed to grow in the woods of Germany in the greatest plenty in the places where charcoal has been made. Hence the good women who collect them to sell, receiving a hint how to encourage their growth, have been accustomed to make fires in certain places of the woods, with heath, broom, vaccinium, and other materials, in order to obtain a more plentiful crop. This strange method of cultivating morels being however sometimes attended with dreadful consequences, large woods having been set on fire and destroyed by it, the magistrate thought fit to interpose his authority, and the practice is now interdicted.

2. The impudicus, stinking morel, or stink-horns, is also a native of Britain, and found in woods and on banks. It arises from the earth under a veil or volva, shaped exactly like a hen's egg, and of the same colour, having a long fibrous radicle at its base. This egg-like volva is composed of two coats or membranes, the space between which is full of a thick, viscid, transparent matter, which, when dry, glues the coats together, and shines like varnish. In the next stage of growth, the volva suddenly bursts into several lacerated permanent segments, from the centre of which arises an erect, white,

cellular, hollow stalk, about five or six inches high and one thick, of a wax-like friable substance, and most fetid cadaverous smell, conical at each end, the base inserted in a white, concave, membranaceous, turbinated cup, and the summit capped with a hollow, conical pileus, an inch long, having a reticulated cellular surface, its base detached from the stalk, and its summit umbilicated, the umbilicus sometimes perforated and sometimes closed. As soon as the volva bursts, the plant begins to diffuse its intolerable odours, which are so powerful and widely expanded, that the fungus may be readily discovered by the scent only, before it appears to the sight.

PHARMACY, is defined the art of preparing, compounding, and preserving medicinals.

The preservation of medicines merely consists in the application of rules for collecting vegetable, animal, and mineral productions, at certain seasons, or under particular circumstances, and of ensuring them against the injuries they would suffer by exposure to light, heat, air, moisture, &c. this, therefore, is the least extensive, and peculiar department of the pharmaceutic art. It is the preparation and composition of medicinals that constitute the principal objects of that science of which we are here to treat.

To prepare medicines, is to produce an artificial arrangement of their constituent principles, by which, either an essential change is effected in their nature, or their medicinal essence is preserved, while their form undergoes a new modification. The first of these effects is invariably the result of chemical action; the latter may be produced by mechanical and chemical agency, either singly or combined.

In the composition of medicines, no chemical union is, in any case, effected; for a change of principle is involved in the term chemical combination; whereas, by compounding medicines, we mean merely the mixing of them together for the purposes of increasing or diminishing, or otherwise modifying, their individual agency, of disguising their taste and odour, or of giving them a more convenient shape.

Pharmacy, then, has the materia medica for its objects, and for its instruments, the means by which mechanical or chemical change is operated upon the ingredients of which the materia medica is composed. The most orderly method, therefore, of considering this subject will be, first to describe the mode in which the component principles of substances are developed, separated and combined, to enumerate such principles, or give the analysis of medicinal articles; and secondly, to detail the individual processes of preparation, separation, and combination, with the general uses and average doses of medicines thus combined, separated, or prepared.

PART I.

Pharmaceutical operations, and general analysis of the different substances used in medicine.

Pulverization is a process too simple and common to require definition; it consists in reducing substances to powder, by beating, or forcibly overcoming the aggregative, in order to facilitate the agency of chemical attraction. In trituration, the same effect is produced by rubbing in place of beating the materials operated upon; when this last is carried to a certain extent, and assisted by the addition of a fluid which does not act chemically upon this material, the process is denominated levigation.

The above processes are facilitated by separating, from time to time, the coarser from the finer parts of the materials: hence the utility of sifting, or passing the powder over sieves with apertures of various diameters: hence likewise the pharmaceutical process of washing, or, as it is termed, elutriation, by which, although in a different mode, the same end is obtained as by sifting, the powder being agitated in a fluid which does not act upon it as a solvent, the larger particles immediately subside, from which the fluid suspending the smaller is poured off, and suffered to remain at rest until these last are all deposited.

Most of the metals are mechanically divided by the operation called granulation; this consists of first filing or beating the metal into fine leaves; or by melting it, and during its state of fusion, pouring it into water, which condenses the separate globules: this process is denominated granulation, on account of the metallic particles being separated in the form of small grains.

The above then are the principal of those mechanical operations which may be regarded as auxiliary or preliminary to such as more immediately promote chemical action, or tend to effect an essential change in bodies: of these last the primary and most important is solution.

Solution, like pulverization, appears at first sight to be a simple process; it is however, in fact, an example of chemical attraction exerted between the particles of a solid and of a fluid substance; and although the solvent or active power is in vulgar conception attributed to the latter, "the attraction whence the solution proceeds is reciprocal, and is not more exerted by the one than by the other." Solution, however, of bodies in water, differs from most cases of chemical combination, in scarcely effecting an actual change in the properties of such bodies. This process therefore may be regarded as, in some measure, an exception to the general law of chemical action. Solution is aided by mechanical division; it is accelerated by agitation, and in most instances proceeds with a rapidity proportionate to the degree of temperature to which the solvent and solvend are subjected; because, by pulverization, agitation, and heat, the power by which the minute particles of individual bodies are held together is weakened, and thus mutual attraction is expedited.

Solution is differently denominated, according to the nature either of the solvent or solvend, or the manner in which the process is effected.

When we have a combination of saline or earthy substances, part of which is only soluble in one, and part in another fluid, the one portion may be separated from the other by the application of its appropriate solvent: such mode of solution is denominated lixiviation, and the result obtained a ley. When a fluid is applied to any vegetable or animal matter, so as to dissolve or attract only part of its principles, the operation is called extraction. If solution is effected without artificial heat, we denominate the process maceration; if a moderate heat is employed, digestion. When boiling fluid is poured upon a substance, and the vessel covered till the solution cools, the operation is termed infusion; and decoction if the fluid is actually boiled upon the materials to be dissolved.

When we wish to obtain the solid matter that has been dissolved, the solution is exposed to heat, converted into vapour, and that part not capable by this degree, or mode of heat, of being volatilized or evaporated, is thus obtained in a solid form: this process is denominated evaporation. Many substances, especially of the saline class, when thus treated, after the evaporating process has been carried to a certain extent, concrete into hard masses, transparent, and of a regular form: such concretions are termed crystals, and the process which engenders them crystallization. Crystals are abundantly formed in nature by slow and spontaneous, in place of a hasty and artificial evaporation; indeed it has recently been argued, that every modification of material substances deserves to be regarded as a crystal. The figure which the body assumes as the result of crystallization is invariable and peculiar to itself. Hence the classification of crystals, according to their form, as into prismatic, rhomboidal, &c. External circumstances, however, often interfere with this regularity.

The transparency of crystals, which is essential to their existence, depends upon a certain quantity of water diffused through them, called therefore their water of crystallization; when this is expelled, by whatever means, the density, pellucidity, and figure of the crystal, are lost. When crystals are thus destroyed, in consequence of exposure to air, they are said to effloresce. When water is absorbed by a crystal, so that it loses its crystalline, and assumes a moist condition, it is said to deliquesce.

Precipitation is another mean by which a solid is separated from a fluid body. If to a solution is added a substance having a more powerful attraction to the fluid than the solvent, the latter will be disunited, and thrown down or precipitated in a solid form; or the added matter may enter into combination with the solvent itself, and produce a compound no longer soluble, which will consequently be in the same manner precipitated.

When from a given solution or mixture, the volatile rather than the fixed or solid matter is wished to be separated, the processes of distillation or sublimation are had recourse to: in the former, the materials are subjected to a given degree of heat in vessels formed so as to collect the vapour, and again condense or reduce it to fluidity; by the latter, the volatile matter is likewise separated, and again condensed, but the reduction is into the state not of fluidity but of solidity.

After solution, fusion is the next in importance of pharmaceutical processes. This operation is usually performed in vessels called crucibles, which are cups formed of black lead, of earthenware, or of some metal, to which heat is applied generally by a furnace. Fusion is employed in order to effect chemical combination among materials which are insoluble, at least in any fluid which does not interfere with their chemical relations. Heat, however, may be applied so as to promote union among bodies, though it is not so powerful as to produce fusion; as for example in calcination, by which, in consequence of exposing a metal to a high temperature, it attracts oxygen from the circumambient air. Deflagration is a process in some measure similar: this consists in mixing substances with which much oxygen is combined, by a feeble attractive power, with inflammable matter, and subjecting the mixture to heat; such substance attracts the oxygen from the matter with which it had previously been united, and thus becomes oxydated or deflagrated.

The above, then, are the chief processes of pharmacy; or those by which the principles of such substances as enter into the materia medica, are developed, combined, and separated. We now proceed to our proposed

Analysis of medicinal articles.

On this subject we shall be as brief as possible. A more ample analysis of the respective substances treated of, will be found under their names as they occur in alphabetical order.

In analysing the different productions of nature, we obtain a few substances which are incapable in our present state of knowledge of further decomposition. These substances are denominated *simple*. As, however, we have no means of ascertaining whether, at any period of decomposition, we have arrived at the ultimate particles of bodies, absolute simplicity can never be predicated of any substance; and by the term simple, we merely mean to express the homogeneousness of any substance, as it relates to our present state of chemical knowledge. See CHEMISTRY.

In the first order of simple substances, and those indeed which appear to prefer the highest claim to the character of simplicity, are the gases, oxygen, azote, and hydrogen; which are solid materials brought into a gaseous condition by caloric.

Of these, oxygen is the most important. Like other gases, it is elastic and invisible; it is a little heavier than common air. Its distinguishing properties or characteristics, are its power of supporting combustion and animal life. The compounds resulting from the union of oxygen with other materials form the most active medicinal agents.

Thus, for example, quicksilver, when in its metallic state, is scarcely possessed of any active properties in reference to the animal economy; on the contrary, when combined with oxygen, it constitutes one of the most powerful agents that are employed in medicine.

Oxygen constitutes nearly one-fourth of atmospheric air; united in a certain proportion with hydrogen, it forms water; and with certain inflammable substances, acids. Indeed the element derives its name from being the acidifying principle. Oxygen, however, unites with many substances without rendering them acid; such are the compounds which this element forms with the metals, as well as with large numbers of both vegetable and animal productions.

Azote, like oxygen, when pure and uncombined, always exists in a gaseous form; this constitutes the remaining three-fourths of the atmosphere. It is lighter than atmospheric air; it is unable to support respiration or combustion; and in the strictest sense it is not inflammable. Combined with oxygen, in a certain proportion, it forms, as just stated, atmospheric air; in that proportion in which the two elements are saturated, it constitutes the nitric acid; with a smaller proportion, the nitrous acid: and we may here observe, that the terminating syllables *ic* and *ous*, are used in all cases to denote the different degrees in which oxygen enters into the composition of acids. Thus sulphur, with a larger quantity of oxygen, so as to constitute it a more perfect acid, is called sulphur*ic*; with a smaller proportion of this principle, it is named sulphure*ous* acid.

Azote, with a certain quantity of oxygen, insufficient to create acidity, forms nitrous and nitrous-oxyd gases, the last of which has been but very recently discovered, and has been celebrated by its extraordinary powers on the animal frame.

Combined with hydrogen, in a given proportion, azote forms ammonia or volatile alkali.

Lastly, azote is an abundant principle in animal matter, and indeed chiefly occasions the variation in composition between this and vegetable substance.

Hydrogen, the last of the simple gases, is extremely light and inflammable; its most important compound is water, formed, as just stated, by its union in a certain proportion with oxygen. Water, it is almost unnecessary to observe, is one of the most important agents in pharmacy.

The next order of those substances which are considered as simple, are the three inflammable principles, carbon, sulphur, and phosphorus.

Carbon is the basis of common charcoal. In this substance, however, it is combined with some oxygen; and it has lately been demonstrated, that the diamond is the pure inflammable base of carbon. Combined with a larger quantity of oxygen, carbon constitutes the gaseous oxide of carbon; when actually saturated with oxygen, it forms the carbonic acid gas, or what was formerly called fixed air. Carbon, united with hydrogen and oxygen, forms several peculiar compounds, such as alcohol, ether, &c.

Sulphur, we have already said, in combination with oxygen, constitutes the sulphuric and sulphureous acids; the latter is extensively employed in chemistry and pharmacy.

Sulphur and hydrogen form a gaseous compound called sulphurated hydrogen, which is distinguished by a peculiar fœtor. Lastly, sulphur is a component principle of several animal, and of some few vegetable, substances.

Phosphorus has not been detected pure and uncombined. In the fossil kingdom, however, it is found combined both with several of the earths and metals; and it also enters into the composition of many animal and vegetable productions.

There are three acids, the muriatic, fluoric, and boracic, which, on account of their not having hitherto been decomposed, are regarded as simple, but which analogy leads us to suppose are constituted in the same manner with other acids, viz. by the union of their peculiar principle with oxygen: it is only the first of these that can be regarded as a pharmaceutic agent. It exists in abundance in sea-salt. When in a gaseous condition, it is remarkably pungent. It is capable of combining with a considerable portion of oxygen, so as to form the oxymuriatic acid, which acts with energy on inflammable substances.

Metals form the third order of simple substances. The distinguishing properties of these are opacity, brilliancy, ductility, fusibility, malleability, and superior specific gravity to that of any other substances. They are rendered active on the system by combination with oxygen or with acids; the most active of them, as we have already observed, being almost inert in a metallic state. Different metals are capable of combining with different quantities of oxygen; four of them, arsenic, molybdena, tungsten, and tin, may be so far oxygenated, as to pass into the form of acids.

The last order of simple substances is the earths. The characters of these are insipidity, infusibility, not being inflammable, and scarcely soluble, saving a specific gravity of less than five to one, and being capable of combination with acids to form neutral salts.

The principal earths are the silex, argil, magnesia, lime, barytes, and strontites. Of these the magnesia and lime are in the most common use as medicines; the argillaceous compounds are not unfrequently employed; and lately the barytic salts have been introduced into practice.

Alkalies bear some resemblance to the earths. They have a penetrating taste; they change the vegetable colours to a green; they powerfully attract water, unite with oils, and with the acids form neutral salts. They are three; potass, soda, and ammonia: the last has been proved to be compounded of azote and hydrogen, and it is probable that the others may ere long be demonstrated to be compound substances.

All the alkalies are employed in medicine; and they are likewise important agents in pharmacy. The names of the neutral salts which are formed by the union of acids with alkalies, earths, and metallic oxides, are chosen partly from the base and partly from the acid. All (for example) of the salts composed of the sulphuric acid, are denominated sulphats; as the sulphat of potass, of lime, &c. When the acid forming the union is less pure, or when it is the sulphureous, the resulting compounds are denominated sulphites; and this principle of nomenclature extends through the whole of saline compositions.

We now proceed to state the proximate and ultimate principles of the vegetable and animal productions of nature; or of those substances which result from organization, in contradistinction to those of inert matter. By the proximate principles of organic matter, we mean those by the combination and separation of which a compound body may be formed or divided. The ultimate principles are the elements of which an integral body may consist, whether more or less complex in its composition.

The proximate principles of vegetables, which substances are the most common objects of pharmacy, may be separated or ana lysed by mere exposure to heat: sometimes the atmospheric air is admitted in conjunction with heat; fermentation is often employed to separate the constituent principles of materials; lastly, nitric acid is much used in analysis, by which oxygen is communicated to the substance operated upon; and by the resulting compound, the nature of the acidifiable base is indicated.

Gum is one of the most abundant among the proximate principles of vegetables. It is glutinous, insipid, without odour, and soluble in water, constituting a viscid solution, denominated mucilage. It is insoluble in alcohol, ether, or oil. It does not absorb oxygen from the atmosphere; it is neither volatile nor fusible. At a temperature beyond the boiling point, but beneath that of ignition, gum is decomposed, and affords an impure acetous acid, ammonia, carbonic acid, and carbonated hydrogen gases; the residuum is charcoal with a certain quantity of lime.

The ultimate principles of gum are oxygen, hydrogen, carbon, azote, and lime. The medicinal qualities of gum are trivial. In pharmacy it is employed principally as a medium of mixture between oils and water.

Resin. This is another proximate principle existing in abundance in vegetable products. It is generally, but not always, united with gum. Resin is not soluble in water, but, unlike gum, is soluble in alcohol, ether, and oils. Resin does not absorb oxygen; when heated to ignition it burns; and is fusible by a heat nearly that of boiling water. When volatilized, however, it is invariably decomposed: its products are water, acetous acid, a burnt oil, and a charcoal residuum. Its ultimate principles are carbon, hydrogen, and oxygen.

Resins are much more active on the living system than gums. The virtues of many medicinal substances depend exclusively on their resinous part.

The extractive matter is another vegetable principle, which until lately was confounded with the gum and resin. This is equally soluble in water and in alcohol. It likewise, at a certain temperature, absorbs oxygen. It affords, upon being exposed to heat, empyreumatic acid and oil, and some ammonia. Its elements are carbon, hydrogen, oxygen, and azote.

This vegetable principle it is difficult to obtain pure and unmixed.

Oil. This is of two kinds, expressed or unctuous, and volatile or essential. These have some qualities in common, and others characteristic of each. Expressed oils are viscid, almost without taste or odour: they congeal by cold, and are insoluble either in water or alcohol. With alkalies they form soap. At a temperature of 212°, they are decomposed, and afford water and carbonic acid. Their ultimate principles are carbon, with a small proportion of hydrogen.

These oils are generally found in the seeds and fruits of vegetables, from which they are separated by mechanical pressure, or by boiling. Some of them have medicinal virtues, but they are commonly employed merely as lubricants.

Volatile or essential oils are quickly dissipated by the heat of boiling water, without suffering decomposition. They are more soluble in alcohol than in water. They slowly absorb oxygen, and are at length changed into resinous matter. They contain more hydrogen than the fixed oils.

Essential oil exists in abundance in the aromatic plants, and appears to constitute their aroma, although some chemists have supposed this last to be a peculiar and exclusive principle. It is usually extracted from the vegetable by distillation. As medicines, these oils are highly stimulant. The natural combination of essential oil and resin, which exists in some plants, constitutes balsam, which in some cases has also a peculiar acid in its composition.

Camphor. This is a distinct vegetable principle. It is insoluble in water, but is soluble in alcohol, oil, and ether. It evaporates even at the ordinary temperature of the atmosphere. When distilled, it is decomposed, and affords a pungent volatile oil, amounting to nearly one-third of its weight, while carbonic and hydrocarbonic acid gases escape, and a quantity of charcoal remains. Camphor then appears to contain a greater proportion of carbon and perhaps of oxygen than the essential oils. The medicinal powers of camphor are very considerable.

Wax is a solid, tenacious, and inflammable principle, holding nearly the same relation to expressed, that camphor does to essential, oil.

Fecula is an important principle in vegetables. It is, when existing separately, mild and insipid. It is not soluble in cold water. With boiling water, it forms a jelly. It is insoluble in alcohol. It is converted by certain processes into sugar. Fecula is composed of oxygen, carbon, and hydrogen. It is by far the most nutritious principle in vegetables.

Gluten. A thick fibrous substance found in the farina of some plants. It is insipid, elastic, insoluble in water, and but sparingly soluble in alcohol. Its prominent principle appears to be azote.

Albumen, like gluten, is named from its resemblance to a principle in animal matter. This is soluble in cold water, and coagulated by heat or alcohol. It affords much ammonia on exposure to heat.

Saccharine matter is generally found united with gum and extract. It is soluble in water, and in alcohol. It is converted by fermentation into alcohol; and this last, by a second stage of fermentation, becomes acetous acid. Saccharine matter consists of oxygen, carbon, and hydrogen.

The saline principle in vegetables is named their essential salt. Essential salts are either acids or neutrals.

The native vegetable acids which have been detected, are seven, viz. the malic, which is contained in apples, and other fruits, previous to their maturity. It is converted into the oxalic acid by the agency of nitrous acid.

The oxalic. This has the largest proportion of oxygen, of any native vegetable acid. It is soluble, and capable of crystallization. Its distinguishing property is its very strong attraction for lime.

The citric. This attracts the earths in general more forcibly than the alkalies.

The tartarous, which is extremely soluble in water, and crystallizable. It has been imagined to contain a larger portion of hydrogen than any other of the acids.

The acetous. This acid is more usually the produce of fermentation. It is however found native in the sap of the vine, &c. It yields upon decomposition a small portion of ammonia.

Benzoic acid is found in several balsams and gum-resins. This is soluble in boiling water, and upon cooling separates in white flakes.

The gallic is the last of the native vegetable acids. This has generally been supposed to constitute the principle of astringency in vegetables. It exists abundantly in gall-nuts, and other vegetable astringents. Its distinguishing property is its forcible attraction to the oxides of iron, with which it forms a precipitate of a very deep black. The gallic acid contains a large quantity of carbon, with some oxygen, and a very small quantity of hydrogen.

The tannin, or tanning principle, has been till lately confounded with the gallic acid. This principle is characterized by its faculty of combining with animal jelly, and forming a hard insoluble substance. Tannin is found in considerable quantity in vegetable astringents, and is usually united with the gallic acid.

Besides the above vegetable acids, several compounds exist in some vegetables, formed by the junction of sulphuric, nitric, muriatic, carbonic, and phosphoric acids, with the alkalies and earths.

The ligneous part, or fibre, of the vegetable, is enumerated among its proximate principles. This is in a manner the basis for the attachment of its other principles. It is insipid and insoluble. With nitrous acid it affords the malic and oxalic acids. It appears to be principally formed of carbon, combined with oxygen and hydrogen.

From the above enumeration of the proximate principles in vegetables, the utility of those pharmaceutical processes to which they are subjected, may with facility be perceived. These we need not again describe; but shall conclude the present section by a general notice of the principles of such animal substances as are medicinally employed. The number of articles which are received into the materia medica from the animal kingdom is comparatively small. Animal have the same general chemical characters with vegetable products. The principal difference is constituted by the superior disposition of the former to undergo the putrefactive process, and by their affording a larger quantity of ammonia or volatile alkali when decomposed by heat: these peculiarities appear to be principally derived, as above noticed, by the presence of azote in a much larger proportion in animal than in vegetable matter. This in decomposition unites with the hydrogen which animal substances likewise contain in abundance, and thus constitutes the ammonia. Animal substances contain likewise sulphur and phosphorus; and for the most part the carbon which enters into their composition is much inferior in quantity to what is found in vegetables.

The vegetable gluten and albumen we have already described as resembling the animal. Animal fat bears a considerable resemblance to vegetable oil. Gelatine is like mucilage or fecula. Milk contains a principle similar to the saccharine matter in the vegetable. A substance having an affinity to resin is found in several animal secretions; and the animal acids do not greatly differ from the vegetable compounds of the same class.

We now proceed to our detail of the individual processes in pharmacy. In so doing we shall pursue the plan adopted by Mr. Murray; of giving, not a translation of each separate process, both from the London and Edinburgh Pharmacopœias; but wherever the formula of the first differs in no essential point from the last, we shall confine ourselves to a statement of this last, and give at the head of the article the name by which it is distinguished in either. We have thus chosen the Edinburgh Pharmacopœia as in a manner the basis of the present article, and this merely on account of its more recent revision than that of the London, and the titles of medicines being made for the most part more conformable to the present improved condition of pharmaceutical chemistry. With the above-mentioned author, however, we shall point out when it occurs, "any important difference either in proportion, composition, or mode of conducting the process," in the directions of the two colleges, and at the end of each division add those preparations which are peculiar to the Pharmacopœia Londinensis.

While thus we shall make the article as brief as the subject will admit of, we shall at the same time, it is presumed, ensure the advantages of a treatise more in detail.

PART II.

THE PREPARATIONS AND COMPOSITIONS OF MEDICINES.

Simplicium quorundam medicamentorum præparationes.

Preparation of some simple medicines.

Carbonas calcis præparatus, prepared carbonat of lime, Ed. Creta præparata, Lond.

Carbonat of lime (whether the softer variety called chalk, or the harder, crab's-stones and crab's-eyes), being reduced to powder in an iron mortar, and levigated on a porphyry-stone, is to be put into a vessel of considerable size, and water poured upon it; after the vessel has been frequently agitated, the water is to be poured off loaded with a fine powder, which, when it has all subsided, is to be dried, and the coarser particles which the water could not suspend are to be again levigated and treated in the same manner.

These calcareous carbonates, which are all of the same nature, are used as antacids. Dose one or two drachms.

Carbonas ferri præparatus, prepared carbonat of iron, Ed. Ferri rubigo, Lond.

Purified iron filings to be frequently moistened with water, till they become rust, which is to be rubbed to a fine powder.

An active chalybeate. Dose from 10 to 20 grains.

Carbonas zinci impurus præparatus, prepared impure carbonate of zinc, Ed. Lapis calaminaris, Lond.

The preparation of impure carbonat of zinc roasted by those who make brass, is to be conducted in the same manner as the carbonat of lime.

This powder is the basis of the common cerate. It is sprinkled on the skin in the cutaneous inflammations of children.

Ferri limatura purificata, purified filings of iron, Ed.

A sieve being placed over the filings, a magnet is to be applied in order to attract the pure iron through its apertures upwards.

Ferri oxidum nigrum purificatum, purified black oxide of iron, Ed.

Let the scales of the black oxide of iron, found at the anvils of workmen, be treated with a magnet in the same manner; for the magnet attracts only the more small and pure scales, leaving those which are larger and less pure.

Oxidum zinci impurum præparatum, prepared impure oxide of zinc, Ed. Tutia, Lond.

To be prepared as the carbonat of lime.

Tutty is employed with the same intention as calamine.

Sulphas aluminæ exsiccatus, dried sulphat of argil, Ed. Alumen ustum, Lond.

Let sulphat of argil be melted in an earthen or iron vessel, and heat applied until the liquid ceases to boil.

This preparation is used as an escharotic.

Sulphur sublimatum lotum, washed sublimed sulphur, Ed. Flores sulphuris loti, Lond.

Take of sublimed sulphur one pound; water four pounds; boil the sulphur a little with the water, then pour the water off, and free the sulphur of acid by the affusion of cold water; lastly, dry the sulphur.

This perhaps is a superfluous process.

Sulphur præcipitatum, Lond.

Take of sulphurated kali (sulphuretum potassæ) six ounces; distilled water one pound and a half; diluted vitriolic (sulphuric) acid as much as necessary; boil the sulphurated kali in the distilled water until it is dissolved: filtre the liquor through paper, and add the diluted acid. Wash the precipitated powder until it becomes insipid.

This preparation of sulphur is from its whiteness useful in forming ointment.

Sulphuretum antimonii præparatum, prepared sulphuret of antimony, Ed. Antimonium præparatum, Lond.

To be prepared in the same manner as carbonate of lime.

Mel despumatum, clarified honey.

Liquify honey in a water-bath, and remove the scum.

Herbarum et florum exsiccatio, drying of herbs and flowers.

Herbs and flowers are to be dried with the gentle heat of a stove, or a common fire, in such a quantity that the exsiccation may be effected as speedily as possible; for in this manner their virtues are best preserved. The indication of this is their retaining their native colour. The leaves of hemlock, and other plants containing a subtle volatile oil, after being dried, are to be rubbed to powder, and preserved in glass-vessels well stopped.

Scilla maritima exsiccata, dried sea-quill, Ed. Scilla exsiccata, Lond.

Let the root of the sea-squill be cut transversely into thin slices, after its external covering has been removed, and dried by a gentle heat.

If when rendered friable, the squill retains its bitterness and acrimony, the drying process has been properly conducted. It is in this state that the squill is chiefly used in medicine. Dose from one to three grains.

Pulparum extractio, extraction of pulps, Ed. Pulparum præparatio, Lond.

Boil those fruits which afford pulp, if unripe or if ripe and dry, with a little water; then express the pulp through a hair-sieve, and gently boil it in an earthen vessel, stirring it frequently lest it burns, until it assumes the consistence of honey. The cassia fistula pulp is to be boiled from the bruised pod, and the water evaporated to a due consistence. When fruits are ripe and fresh, the pulp may be squeezed through a sieve without previous boiling.

The following preparations are only found in the London Pharmacopœia:

Ammoniaci purificatio, purification of gum ammoniac.

Boil impure ammoniac in water until it softens, and by a press strain it through a hempen bag: let the resinous matter have time to subside. Evaporate the water, mixing towards the end of the evaporation the resinous and gummy parts. Assafœtida and other similar gum-resins may be purified in the same way. Any gum also which melts easily, such as galbanum, may be purified by putting it into an ox-bladder and keeping it in boiling water, till it becomes so soft that it may be pressed through strong linen cloth, and freed from its impurities.

Styracis purificatio, purification of storax.

Having dissolved storax in alcohol, strain the liquor, and distil it with a gentle heat to a proper consistence.

Cornu cervi ustio, burning of hartshorn.

Burn pieces of hartshorn until they become white, then rub them to a very fine powder.

Millepedæ præparatio, preparation of millepedes.

Suspend these, inclosed in a thin linen bag, over proof spirit heated in a close vessel, that they may be killed by the vapour, and rendered friable.

Spongiæ ustio, burning of spunge.

Bruise spunge cut into small pieces; and when freed from strong matter, burn it in a close iron vessel until it becomes black and friable; then rub it into a fine powder.

Conservæ, conserves.

The conserves that are retained in the Ph. Ed. are the conserva corticis exterioris recentis fructus citri aurantii, radulâ abrasa; conserve of the outer rind of the orange, rasped by a grater, Ed. Conserva aurantii hispanionalis corticis exterioris, Lond. Conserva fructûs rosæ caninæ maturi, a seminibus eorumque pube sollicitè purgati, conserve of the fruit of dog-hips carefully freed from the seeds and included down, Ed. Conserva cynosbati, Lond.

Conserva rosæ gallicæ nondum explicitorum, conserve of the unblown petals of the red rose, Ed. Conserva rosæ rubræ, Lond.

In each of these the vegetable is to be beat into a pulp, and during the beating three times its weight of sugar to be gradually added.

In addition to the above, the London college retain conserva absinthii maritimi, conserve of sea-wormwood. Conserva lujulæ, conserve of wood-sorrel. Conserva ari, conserve of arum. Conserva pruni sylvestris, conserve of sloes. Conserva scillæ, conserve of squills.

Succi, juices.

Succus cochleariæ officinalis compositus, compound juice of scurvy-grass, Ed. Succus cochleariæ compositus, Lond.

Take of juice of scurvy-grass, juice of water-cresses expressed from recently gathered herbs, juice of the orange-fruit, of each two pounds; spirit of nutmeg half a pound: mix and let them stand until the impurities have subsided, then pour off the liquor.

This preparation is scarcely in use.

Succi inspissati, inspissated juices or extracts.

Succus spissatus aconiti napelli, inspissated juice of aconite or wolfsbane, Ed.

Bruise the fresh leaves, and press the juice strongly through a hempen bag; which reduce, by evaporation in open vessels heated by boiling water saturated with muriat of soda, to the consistence of thick honey. After the mass has cooled, it is to be kept in glazed earthen vessels, and moistened with alcohol.

A remedy chiefly employed in obstinate cases of chronic rheumatism. Dose from five to six or more grains.

In the same manner are to be prepared the four following:

Succus spissatus atropæ belladonnæ, inspissated juice of deadly-nightshade.

This has been used in convulsive disorders and in schirrus. Dose one grain, gradually increased.

Succus spissatus conii maculati, inspissated juice of hemlock, Ed. Succus spiss. cicutæ, Lond.

Recommended by Störk of Vienna in schirrus and cancer. Dose two grains, increased largely.

Succus spissatus hyoscyami nigri, inspissated juice of black henbane, Ed.

Dose one grain, increased.

Succus spissatus lactusæ virosæ, inspissated juice of strong-scented lettuce, Ed.

Principally used in Germany for dropsy. Dose four or five grains, largely increased.

Succus spissatus sambuci nigræ, inspissated juice or rob of elder, Ed. Succus spiss. baccæ sambuci, Lond.

Five pounds of elder-berry juice, and one pound of sugar, are to be gently boiled to the consistence of thick honey.

This is by no means an eligible preparation. It has been employed as a laxative, in the dose of half an ounce or more.

Succus spissatus momordicæ elaterii, inspissated juice of wild cucumber, Ed. Elaterium, Lond.

Cut the ripe fruit of the wild cucumber, and pass the expressed juice through a very fine hair sieve. Boil it a little, and set it aside for some hours, that the thick parts may subside. Pour off the thinner parts, and then separate the remainder by straining. The thicker part which remains is to be covered with a linen cloth, and dried by a gentle heat.

This preparation has been employed as a powerful cathartic. Dose one or two grains.

The additional preparations in the Ph. Lond. are, succus spissatus ribis nigri, inspissated juice of black currant; and succus spissatus limonis, inspissated juice of lemon.

Olea fixa, fixed oils.

Oleum amygdalæ communis, Ed. Ol. amygdalæ, Lond.

Take any quantity of fresh almonds, bruise them in a stone motrar, enclose the mass in a hempen bag, and express the oil by a press without heat.

In the same manner the oleum lini usitatissimi, oil of linseed, Ed.; ol. e semine lini, Lond. is to be expressed.

To the above, the London college add, ol. ricini, castor-oil; and ol. sinapeos, oil of mustard.

The former of these, however, is usually prepared by decoction, and is made in the West Indies.

Emulsiones, emulsions.

Emulsio amygdalæ communis, almond emulsion, Ed. Lac amygdalæ, Lond.

Take of sweet almonds (blanched) an ounce; water two pounds and a half; beat the almonds in a stone mortar, and gradually add the water, then strain.

This emulsion is employed freely as a demulcent.

Emulsio gummi mimosæ niloticæ, Arabic emulsion.

This is prepared in the same manner, adding while beating the almonds two ounces of gum-arabic mucilage.

Employed with the same intention as the above.

Emulsio camphorata, camphor emulsion.

Camphor one scruple, blanched sweet almonds two drachms, refined sugar one drachm, water six ounces; to be mixed in the same manner as the almond emulsion. Dose two ounces.

Infusa, infusions.

Infusum cinchonæ officinalis, infusion of Peruvian bark.

Take of Peruvian bark powdered one ounce; water one pound. Macerate for four-and-twenty hours, and then strain.

This contains only a small portion of the active principle of the bark. Dose two ounces.

Infusum digitalis purpureæ, infusion of foxglove.

Take of the dried leaves of foxglove one drachm; boiling water eight ounces; spirit of cinnamon one ounce. Macerate for four hours, and strain. Dose in dropsy half an ounce twice a day, gradually increased.

Infusum gentianæ luteæ compositum, compound infusion of gentian, Ed. Infus. gentianæ comp. Lond.

Take of gentian root half an ounce; dried orange-peel one drachm; coriander-seeds half a drachm; diluted alcohol four ounces; water one pound. Pour on first the alcohol, and after three hours the water; then macerate for twelve hours without heat, and strain.

An useful medicine in dyspepsia. Dose two ounces.

Infusum mimosæ catechu, infusion of catechu.

Take of extract of catechu two drachms and a half; cinnamon half a drachm; boiling water seven ounces; simple syrup one ounce. Macerate the extract and cinnamon with the water in a close vessel for two hours; then strain, and add the syrup.

Principally employed in diarrhœa. Dose one ounce.

Infusum rhei palmati, infusion of rhubarb.

Take of rhubarb root half an ounce; boiling water eight ounces; spirit of cinnamon one ounce. Macerate the root with the water in a closed vessel for twelve hours; then, the spirit being added, strain the liquor.

Employed as a mild cathartic. Dose two ounces.

Infusum rosæ gallicæ, infusion of red rose, Ed. Infus. rosæ, Lond.

Take of the dried petals of the rose two ounces; boiling water five pounds; sulphuric acid one drachm; refined sugar two ounces. Macerate the rose with the water in an earthen vessel (which is not glazed with lead) for twelve hours; then, having poured on the acid, strain the liquor and add the sugar.

Principally used as a mild astringent gargle.

Infusum tamarindæ indicæ cum cassia senna, infusion of tamarind and senna.

Take of the prepared fruit of the tamarind one ounce; senna-leaves one drachm; coriander-seeds half a drachm; unrefined sugar half an ounce; boiling water eight ounces. Macerate in a closed earthen vessel not glazed with lead, which is to be shaken frequently, and after four hours standing, the liquor is to be strained.

This is a mild and pleasant purgative. The whole of the above quantity may be taken at a time.

N. B. The infusum sennæ simplex of the Ph. Lond. is prepared from senna one ounce and a half; ginger one drachm; boiling water one pint; macerated for an hour and strained.

The infusum sennæ tartarisatum, is prepared from senna one ounce; coriander-seeds bruised half an ounce; acidulous tartrite of potass (crystals of tartar) two drachms; distilled water one pint: the crystals of tartar to be dissolved in the water by boiling, and the liquor while hot poured on the senna and coriander, the maceration being continued for an hour in a covered vessel, and when cold strained. Dose of each from two to eight ounces.

Potio carbonatis calcis, chalk potion, Ed. Mistura cretacea, Lond.

Take of prepared carbonate of lime an ounce; refined sugar half an ounce; mucilage of gum arabic two ounces. Rub them together, and gradually add two pounds and a half of water, and spirit of cinnamon two ounces.

An antacid. Dose one or two ounces.

The four following mixtures are found only in the Ph. Lond.

Mistura camphorata, camphorated mixture.

Take of camphor one drachm; a small quantity of rectified spirit of wine; refined sugar half an ounce; boiling distilled water one point. Rub the camphor first with the spirit, then with the sugar; add gradually the water, and strain the mixture.

Dose an ounce.

Mistura moschata, musk mixture.

Take of musk two scruples; powdered gum arabic, refined sugar, of each a drachm; rose-water six ounces. Rub the musk with the sugar, then with the gum, and gradually add the rose-water. Dose an ounce.

Lac ammoniaci, milk of gum ammoniac.

Take of gum ammoniac two drachms; distilled water half a pint. Triturate the gum with the water poured on gradually.

Dose from half an ounce to an ounce.

Lac assafœtidæ, milk of assafœtida.

Prepared in the same manner. Dose half an ounce or more.

Mucilago amyli, starch mucilage, Ed. Mucilago amyli, Lond.

Take of starch half an ounce; water one pound. Rub the starch, and add gradually the water; then boil them for a short time.

Principally employed as a vehicle for opium, &c. in enema.

Mucilago astragali tragacanthæ, mucilage of gum tragacanth, Ed. Mucilago tragacanthæ, Lond.

Take of tragacanth gum powdered an ounce; boiling water eight ounces. Macerate for twenty-four hours, and rub carefully the gum so that it may be dissolved; then strain it through linen.

Used chiefly in making troches.

Mucilago mimosæ niloticæ, mucilage of gum arabic, Ed. Mucilago gummi arabici, Lond.

Take of powdered gum arabic one part; boiling water one part. Digest with frequent shaking until the gum is dissolved; then strain through linen.

Employed principally as a demulcent, and as a vehicle for suspending oils, &c.

Mucilago seminum cydonii mali, Lond. mucilage of quince-seed.

Take of quince-seed one drachm; distilled water eight ounces. Boil with a gentle heat for ten minutes, and strain through linen.

This is seldom employed in medicine.

Aqua calcis, lime-water, Ed. Aq. calcis, Lond.

Take of lime recently prepared half a pound. Place it in an earthen vessel, and sprinkle it with four ounces of water, keeping the vessel covered while the lime becomes hot and pulverizes; then pour on twelve pounds of water, and by agitation mix it with the lime. This agitation is to be repeated after the lime has subsided, which is to be done about ten times, keeping the vessel closed to prevent the accession of air. Now let the water be strained through paper, interposing glass rods between the filtre and the funnel, that it may pass through as quickly as possible. It is to be kept in bottles well stopped.

Lime-water is used as a tonic and astringent. Dose from one to two pounds daily.

Decocta, decoctions.

Decoctum althææ officinalis, decoction of althæa, Ed.

Take of althæa-root dried four ounces; raisins freed from their seeds two ounces; water seven pounds. Boil down to five pounds; strain; put aside the strained liquor until the impurities have subsided, and pour off the clear liquor.

As a demulcent to be drunk ad libitum.

Decoctum anthemidis nobilis, decoction of camomile.

Take of dried camomile flowers an ounce; caraway-seeds half an ounce; water five pounds. Boil for a quarter of an hour, and strain.

The decoctum pro enemate, and decoctum pro fomento, of the London Ph. are similar to the above.

Decoctum cinchonæ officinalis, decoction of Peruvian bark, Ed. Decoctum cinchonæ, Lond.

Take of Peruvian bark in powder one ounce; water a pound and a half. Boil for ten minutes in a closed vessel, and while still hot strain. Dose two ounces.

Decoctum daphnes mezerei, decoction of mezereon, Ed.

Take of the mezereon-bark two drachms; of bruised liquorice-root half an ounce; water three pounds. Boil with a gentle heat down to two pounds, and strain.

This decoction has chiefly been given in cases of syphilis, either with or without mercury. Dose six or eight ounces.

Decoctum geoffrææ inermis, decoction of cabbage-tree bark, Ed.

Take of the cabbage-tree bark in powder an ounce; water two pounds. Boil gently to one pound, and strain.

This is sometimes given as an anthelmintic. Dose two ounces.

Decoctum guaiaci officinalis compositum, compound decoction of guaiac.

Take of the shavings of guaiac-wood three ounces; raisins two ounces; sassafras-root, liquorice-root, of each an ounce; water ten pounds. Boil the water with the guaiac and raisins with a gentle heat to five pounds, and towards the end of the decoction add the roots; then strain without expression.

It is chiefly given in chronic rheumatism. Dose two or three pints daily.

Decoctum ordei distichi, decoction of barley, Ed. Decoct. hordei, Lond.

Take of pearl-barley two ounces; water five pounds. First wash off with cold water the flour adhering to the barley; then boil the barley for a short time with about half a pound of water, to extract the colouring matter. Put the barley thus purified into five pounds of boiling water. Boil this to one half, and strain.

A common diluent in fever. In the Ph. Lond. a compound decoction is ordered with figs, raisins, and liquorice.

Decoctum polygalæ senegæ, decoction of seneka.

Take of seneka-root one ounce; water two pounds. Boil to sixteen ounces, and strain.

Dose two or three ounces.

Decoctum smilacis sarsaparillæ, decoction of sarsaparilla, Ed. Decoct. sarsaparillæ, Lon.

Take of cut sarsaparilla six ounces; water eight pounds. Digest for two hours in a heat of about 195°; then take out the root and bruise it, return it to the liquor, and boil it with a gentle fire to two pounds. Then express and strain.

Sarsaparilla in this form is employed in combination with mercury in syphilis.

The decoctions of the London, which are not in the Ed. Ph. are the following:

Decoctum cornu cervi, decoction of hartshorn.

Take of burnt and prepared hartshorn two ounces; gum arabic six drachms; distilled water three pounds. Boil, stirring constantly, down to two pounds, and strain.

This is a useless preparation.

Decoctum hellebori albi, decoction of white hellebore.

Take of white hellebore root in powder one ounce; distilled water two pints; rectified spirit of wine two ounces. Boil the water with the root to one pint, and when the liquor is cold, strain it and add the spirit.

This is principally employed as a wash in psora.

Decoctum sarsaparillæ compositum, compound decoction of sarsaparilla.

Take of sarsaparilla root slit and bruised six ounces; bark of sassafras root, shavings of guaiac wood, liquorice root bruised, of each one ounce; mezereon three drachms; distilled water ten pints. Macerate for six hours with a gentle heat; boil to five pints; towards the end of the boiling add the mezereon, and then strain.

An improvement upon the Lisbon diet-drink. Dose four or six ounces, three or four times a day.

Decoctum ulmi, decoction of elm.

Take of the elm bark, fresh bruised, four ounces; distilled water four pints. Boil to two pints, and strain.

This has been used in cutaneous affections.

Syrupi, syrups.

Syrupus simplex, common syrup.

Take of refined sugar, powdered, fifteen parts; water eight parts. Dissolve the sugar with a gentle heat, and boil it a short time, so as to form syrup.

Syrupus acidi acetosi, acidulous syrup.

Take of acetous acid two pounds and a half; refined sugar three pounds and a half. Boil so as to form syrup.

Syrupus althææ officinalis, syrup of althæa, Ed. Syr. althææ, Lond.

Take of fresh althæa root cut, one pound; water ten pounds; refined sugar four pounds. Boil the water with the root to one-half, and strain it by strong pressure. Put aside the strained liquor, that the impurities may subside; and to the purified liquor add the sugar: then boil, so as to form a syrup.

This is a superfluous preparation.

Syrupus amomi zinziberis, syrup of ginger, Ed. Syrupus ziniziberis, Lond.

Take of ginger root beaten three ounces; boiling water four pounds; refined sugar seven pounds and a half. Macerate the root in the water in a closed vessel for twenty-four hours: then to the strained liquor add the pounded sugar, so as to make a syrup.

This is a pleasant and useful syrup.

Syrupus citri aurantii, syrup of orange-peel, Ed. Syr. corticis aurantii, Lond.

Take of the fresh outer rind of the orange six ounces; boiling water three pounds;

refined sugar four pounds. Macerate the rind in the water for twelve hours; then to the strained liquor add the pounded sugar; and thus form a syrup, by applying a gentle heat.

This syrup, like the former, is grateful and aromatic.

Syrupus citri medicæ, syrup of lemon, Ed. Syr. limonis, Lond.

Take of the juice of lemons strained, after the impurities have subsided, three parts; refined sugar five parts. Dissolve the sugar so as to form a syrup.

This syrup is used to sweeten and acidulate mixtures.

Syrupus colchii autumnalis, syrup of colchium.

Take of the fresh root of colchium, sliced into small pieces, one ounce; acetous acid sixteen ounces; purified sugar twenty-six ounces. Macerate the root in the acid for two days, occasionally agitating the vessel: then strain it with a gentle pressure; to the strained liquor add the sugar, and boil it so as to form a syrup.

This has been given in dropsy, in the dose of from half an ounce to one ounce.

Syrupus dianthi caryophilli, syrup of clove July-flower, Ed. Syrup caryophilli rubri, Lond.

Take of the fresh petals of this flower, freed from the peels, one pound; boiling water four pounds; refined sugar seven pounds. Macerate the petals in the water for twelve hours; then, when the liquor is strained, add the pounded sugar, which is to be dissolved with a gentle heat, so as to form a syrup.

This syrup is of a deep red colour, and pleasant flavour.

Syrupus papaveris somniferi, syrup of white poppy. Syrup papaveris albi, Lond.

Take of the dried capsules of the white poppy, freed from the seeds, two pounds; boiling water thirty pounds; refined sugar four pounds. Macerate the sliced capsules in the water for twelve hours; then boil until only a third part of the liquor remains; then strain by strong pressure. Boil the strained liquor to one-half, and again strain: the sugar being then added boil a little, so as to form a syrup.

This syrup is given principally as an anodyne to children. Dose to a child a year old one drachm.

Syrupus rhamni cathartici, syrup of buckthorn, Ed. Syr. spinæ cervinæ, Lond.

Take of the clarified juice of ripe buckthorn-berries two parts; refined sugar one part. Boil so as to make syrup.

This is given as a cathartic. Dose an ounce to an ounce and a half.

Syrupus rosæ gallicæ, syrup of red rose.

Take the dried petals of the red rose seven ounces; boiling water five pounds; purified sugar six pounds. Macerate the petals in water for twelve hours; then boil them a little, and strain; to the strained liquor add the sugar, and again boil it, so as to make syrup.

This syrup is not in much use; it is very slightly astringent.

Syrupus rosæ centifoliæ, syrup of damask, or pale, rose, Ed. Syr. rosæ, Lond.

Take fresh petals of the pale rose one pound; boiling water four pounds; refined sugar three pounds. Macerate the petals in the water for twelve hours: having strained the liquor, add the sugar, and boil so as to form syrup.

A mild purgative given to infants, in the quantity of two or three tea-spoonfuls.

Syrupus scillæ maritimæ, syrup of squill.

Take of the vinegar of squill two pounds; pounded refined sugar three pounds and a half. Let the sugar be dissolved in the vinegar by a gentle heat.

An active expectorant. Dose one or two drachms.

Syrupus toluiferæ balsami, syrup of tolu balsam, Ed. Syr. tolutani, Lond.

Take of common syrup two pounds; tincture of tolu one ounce. To the syrup recently prepared and taken from the fire, add by degrees the tincture, and gently agitate them together.

This syrup is only to be valued from its flavour.

Syrupus violæ odoratæ, syrup of violet, Ed. Syr. violæ, Lond.

Take of the fresh flowers of the sweet-scented violet one pound; boiling water four pounds; purified sugar seven pounds and a half. Macerate the flowers in the water for twenty-four hours, in a covered glass or earthen vessel; then strain without expression, and add pounded sugar, so as to form syrup.

A mild laxative. Dose to infants one or two tea-spoonfuls. The London Pharmacopœia has the syrupus succi fructus mori, syrup of mulberry-juice. Syrupus succi fructus rubi idæi, syrup of raspberry-juice. Syrupus succi fructus ribis nigri, syrup of black currant juice. Syrupus croci, syrup of saffron. Syrupus papaveris, syrup of red poppy. The two last are principally employed on account of their colour. The mel acetatum, oxymel colchici, mel rosæ, mel scillæ, oxymel scillæ, vary but little from their corresponding syrups.

Vina, wines.

Vinum aloes socotorinæ, wine of socotorine aloes, Ed. Vin. aloes, Lond.

Take of socotorine aloes powdered an ounce; lesser cardamom seeds, ginger root, of each contused, one drachm; Spanish white wine two pounds. Digest for seven days, frequently agitating, and strain.

A stimulating cathartic. Dose from one or two drachms to an ounce.

Vinum gentianæ compositum, compound gentian wine.

Take of gentian root half an ounce; Peruvian bark one ounce; orange-peel dried two drachms; canella bark one drachm; diluted alcohol four ounces; Spanish white wine two pounds and a half. The root and barks being bruised, pour first on them the diluted alcohol, and after four-and-twenty hours add the wine. Macerate for seven days, and strain.

Dose, as a stomachic, half an ounce, or six drachms.

Vinum ipecacuanhæ, ipecacuan wine, Ed. Vin. ipecac. Lond.

Take of ipecacuan root bruised one ounce; Spanish white wine fifteen ounces. Macerate, and after seven days strain through paper. Dose as an emetic one ounce.

Vinum nicotianæ tabaci, tobacco wine.

Take of tobacco leaves one ounce; Spanish white wine one pound. Macerate, and after seven days strain through paper.

Dose, as a diuretic, thirty drops increased.

Vinum rhei palmati, rhubarb wine.

Take of the rhubarb root cut two ounces; canella bark one drachm; diluted alcohol two ounces; Spanish white wine fifteen ounces. Macerate for seven days, and strain through paper.

Dose from half an ounce to one ounce.

Aceta, vinegars.

Acetum aromaticum, aromatic vinegar.

Take of the rosemary tops dried, the dried leaves of sage, of each four ounces; lavender flowers dried two ounces; cloves two drachms; distilled acetous acid eight pounds. Macerate for seven days, and strain the expressed liquor through paper.

Principally employed as a perfume.

Acidum acetosum camphoratum, camphorated acetous acid.

Take of the stronger acetous acid six ounces; camphor half an ounce; alcohol as much as is sufficient. Rub the camphor into powder with the alcohol, which put into the acid, so as to dissolve it.

A grateful stimulant, snuffed up the nostrils.

Acetum scillæ maritimæ, vinegar of squill, Ed. Acet. scillæ, Lond.

Take of dried squill two ounces; distilled acetous acid two pounds and a half; alcohol three ounces. Macerate the squill with the vinegar for three days, then express it; add the alcohol; and when the impurities have subsided pour off the liquor.

Dose from one to two drachms.

Tincturæ, tinctures.

Tinctura aloes socotorinæ, tincture of aloes, Ed. Tinct. aloes, Lond.

Take of powdered socotorine aloes half an ounce; extract of liquorice an ounce and a half; alcohol four ounces; water one pound. Digest with a gentle heat for seven days in a closed vessel, frequently shaking it (which is to be observed in the preparation of all tinctures).

Dose one ounce, as a cathartic.

Tinctura aloes ætherea, etherial tincture of aloes.

Take of myrrh, socotorine aloes, of each an ounce and a half; English saffron one ounce; spirit of sulphuric æther one pound. Digest the myrrh with the spirit for four days in a closed vessel; then add the aloes and saffron. Again digest for four days; and when the fæces have subsided pour off the tincture.

Dose one or two drachms.

Tinctura aloes cum myrrhâ, tincture of aloes with myrrh, Ed. Tinct. aloes comp. Lond.

Take of powdered myrrh two ounces; alcohol one pound and a half; water half a pound. Mix the alcohol with the water, then add the myrrh. Digest for four days, and now add an ounce and a half of socotorine aloes, and one ounce of English saffron; again digest for three days, and pour off the pure tincture.

Tinctura amomi repentis, tincture of cardamom, Ed. Tinct. cardamom, Lond.

Take of cardamom seeds four ounces; diluted alcohol two pounds and a half. Digest for seven days, and strain through paper.

This is a grateful aromatic. In the London Ph. a compound tincture of cardamom is ordered, in which are introduced caraway, cinnamon, and raisins.

Tinctura aristolochiæ serpentariæ, tincture of snake root, Ed. Tinct. serpent. Lond.

Take of snake root two ounces; cochineal one drachm; diluted alcohol two pounds and a half. Digest for seven days, and filtre through paper.

Dose two drachms.

Tinctura assafœtidæ, tincture of assafœtida, Ed. Tinct. assafœtid. Lond.

Take of assafœtida four ounces: alcohol two pounds and a half. Digest for seven days, and strain through paper.

Dose one drachm.

Tinctura benzoes composita, compound tincture of benzoin, Ed. Tinct. benz. c. Lond.

Take of benzoin three ounces; Peruvian balsam two ounces; hepatic aloes half an ounce; alcohol two pounds. Digest for seven days, and strain.

This tincture is in vulgar use to recent wounds.

Tinctura camphoræ, tincture of camphor, Ed. Spiritus camphoratus, Lond.

Take of camphor one ounce; alcohol one pound. Mix so as the camphor may be dissolved.

A stimulant embrocation.

Linimentum camphoræ, camphor liniment, Lond.

Take of camphor two ounces; water of ammonia six ounces: spirit of lavender sixteen ounces. Mix the spirit, and water of ammonia; and distil from a glass retort, with a gentle heat, sixteen ounces.

This liniment is more powerful than the preceding.

Tinctura cassiæ sennæ composita, tincture of sennæ, Ed. Tinct. sennæ, Lond.

Take of senna leaves two ounces; jalap root one ounce; coriander seeds half an ounce; diluted alcohol three pounds and a half. Digest for seven days, and to the tincture filtred through paper add four ounces of refined sugar.

Dose an ounce.

Tinctura castorei, tincture of castor, Ed. and Lond.

Take of Russian castor an ounce and a half; alcohol one pound. Digest for seven days, and strain through paper.

In the London Ph. diluted alcohol is employed. Dose one drachm.

Tinctura castorei composita, compound tincture of castor.

Take of Russian castor an ounce; assafœtida half an ounce; ammoniated alcohol one pound. Digest for seven days, and filtre through paper.

Dose one drachm.

Tinctura cinchonæ officinalis, tincture of Peruvian bark, Ed. Tinct. cinchonæ, Lond.

Take of Peruvian bark powdered four ounces; diluted alcohol two pounds and a half. Digest for seven days, and filtre through paper.

Dose two drachms.

Tinctura cinchonæ composita, compound tincture of Peruvian bark, Lond.

Take of Peruvian bark powdered two ounces and a half; dried orange-peel one ounce and a half; Virginian snake root three drachms; saffron one drachm; cochineal in powder two scruples; proof spirit twenty ounces. Digest for four days, and strain.

This is the Huxham's tincture. Dose two or three drachms.

Tinctura cinchonæ ammoniata, ammoniated tincture of bark, Lond.

Take of powdered Peruvian bark four ounces; compound spirit of ammonia two pounds. Digest in a close vessel for ten days, and strain.

This is an improper preparation.

Tinctura colombæ, tincture of colombo, Ed. Tinct. colombæ, Lond.

Take of colombo root, beaten into powder, two ounces; diluted alcohol two pounds. Digest for seven days, and strain.

Dose two or three drachms.

Tinctura convolvuli jalapæ, tincture of jalap, Ed. Tinct. jalapæ, Lond.

Take of jalap in powder three ounces; diluted alcohol fifteen ounces. Digest for seven days, and filtre through paper.

Tinctura croci, tincture of saffron.

Take of English saffron an ounce; diluted alcohol fifteen ounces. Digest for seven days, and filtre through paper.

This tincture has perhaps no other virtue but that of colour.

Tinctura digitalis purpureæ, tincture of foxglove.

Take of the leaves of foxglove dried an ounce; diluted alcohol eight ounces. Digest for seven days, and strain through paper.

A most active and useful medicine. Dose ten grains, gradually increased.

Tinctura gentianæ composita, compound tincture of gentian, Edin. and Lond.

Take of the gentian root two ounces; orange-peel an ounce; canella bark half an ounce; cochineal half a drachm; diluted alcohol two pounds and a half. Digest for seven days, and filtre through paper.

Dose two or three drachms.

Tinctura guaiaci, tincture of guaiac.

Take of guaiac resin one pound; alcohol two pounds and a half. Digest for seven days, and filtre through paper.

Dose two or three drachms.

Tinctura guaiaci ammoniata, ammoniated tincture of guaiac, Ed. and Lond.

Take of guaiac resin four ounces; ammoniated alcohol a pound and a half. Digest for seven days, and filtre through paper.

This is a useful tincture in chronic rheumatism. Dose from one to three drachms.

Tincturi hellebori nigri, tincture of black hellebore, Ed. and Lond.

Take of black hellebore root four ounces; cochineal half a drachm; diluted alcohol two pounds and a half. Digest for seven days, and filtre through paper.

Dose one drachm.

Tinctura hyoscyami nigri, tincture of black henbane.

Take of black henbane leaves dried an ounce; diluted alcohol eight ounces. Digest for seven days, and strain through paper.

Tinctura kino, tincture of kino.

Take of kino two ounces, diluted alcohol one pound a half.

Dose a drachm.

Tinctura lauri cinnamomi, tincture of cinnamon, Ed. Tinct. cinnam. Lond.

Take of cinnamon bark three ounces; diluted alcohol two pounds and a half. Digest for seven days, and strain through paper.

Tinctura lauri cinnamomi composita, compound tincture of cinnamon, Ed. Tinct. cin. comp. Lond.

Take of the cinnamon bark and cardamom seeds, of each an ounce; long pepper two drachms; diluted alcohol two pounds and a half. Digest for seven days, and strain through paper.

Tinctura meloes vesicatorii, tincture of cantharides, Ed. Tinct. cantharidis, Lond.

Take of cantharides one drachm; diluted alcohol one pound. Digest for seven days, and strain through paper.

Dose internally from fifteen to thirty drops.

Tinctura mimosæ catechu, tincture of catechu, Ed. Tinct. catechu, Lond.

Take of catechu three ounces; cinnamon two ounces; diluted alcohol two pounds and a half. Digest for seven days, and strain through paper.

Dose one drachm.

Tinctura myrrhæ, tincture of myrrh, Ed. and Lond.

Take of bruised myrrh three ounces; alcohol twenty ounces; water ten ounces. Digest for seven days, and filtre through paper.

Tinctura opii, tincture of opium, Ed. and Lond.

Take of opium two ounces; diluted alcohol two pounds. Digest for seven days, and filtre through paper.

Dose from fifteen to twenty-five drops.

Tinctura opii ammoniata, ammoniated tincture of opium.

Take of the acid of benzoin, and English saffron, of each three drachms; opium two drachms; volatile oil of anise half a drachm; ammoniated alcohol sixteen ounces. Digest for seven days in a closed phial, and filtre through paper.

Dose from half a drachm to a drachm.

Tinctura opii camphorata, camphorated tincture of opium, Lond.

Take of hard purified opium powdered, benzoin flowers, of each one drachm; camphor two scruples; oil of anise one drachm; proof spirit two pounds by measure. Digest for ten days, and strain.

This is the elixir paregoric. Dose one or two drachms.

Tinctura rhæi palmati, tincture of rhubarb, Ed. Tinct. rhabarbari, Lond.

Take of the rhubarb root three ounces; lesser cardamoms half an ounce; diluted alcohol two pounds and a half. Digest for seven days, and strain through paper.

Dose half an ounce.

Tinctura rhæi cum aloe, tincture of rhubarb and aloes.

Take of rhubarb root ten drachms; socotorine aloes six drachms; lesser cardamoms half an ounce; diluted alcohol two pounds and a half. Digest for seven days, and strain through paper.

Dose six drachms.

Tinctura rhæi cum gentiana, tincture of rhubarb with gentian.

Take of rhubarb root two ounces; gentian root half an ounce; diluted alcohol two pounds and a half. Digest for seven days, and strain through paper.

Dose from two to four drachms.

Tinctura rhabarbari composita, compound tincture of rhubarb, Lond.

Take of cut rhubarb two ounces; bruised liquorice half an ounce; ginger in powder, and saffron, of each two drachms; distilled water one pound; proof spirit twelve ounces. Digest for fourteen days, and strain.

Dose half an ounce.

Tinctura saponis, tincture of soap, Ed. Linimentum saponis compositum, Lond.

Take of soap four ounces; camphor two ounces; essential oil of rosemary half an ounce; alcohol two pounds. Digest the soap in the alcohol for three days; then, the liquor being strained, add the camphor and oil, agitating the liquor.

Tinctura saponis cum opio, tincture of soap with opium.

To be made in the same manner with the last, only adding from the beginning an ounce of opium.

Tinctura toluiferæ balsami, tincture of tolu balsam, Ed. Tinct. bals. tolut. Lond.

Take of tolu balsam one ounce and a half; alcohol one pound. Digest until the balsam is dissolved, and strain through paper.

Tinctura veratri albi, tincture of white hellebore.

Take of white hellebore root eight ounces; diluted alcohol two pounds and a half. Digest for seven days, and filtre through paper.

This is too violent for internal administration.

The following are tinctures peculiar to the Ph. Lond.

Tinctura corticis aurantii, tincture of orange-peel.

Take of fresh orange-peel three ounces; proof spirit two pounds. Digest for three days, and strain.

Tinctura balsami Peruviani, tincture of Peruvian balsam

Take of Peruvian balsam four ounces; rectified spirit one pound. Digest until the balsam is dissolved.

Tinctura cascarillæ, tincture of cascarilla.

Take of cascarilla in powder four ounces; proof spirit two pounds. Digest with a gentle heat for eight days, and strain.

Tinctura galbani, tincture of galbanum.

Take of galbanum cut into small pieces two ounces; proof spirit two pounds. Digest with a gentle heat for eight days, and strain.

Dose one to two drachms.

Tinctura sabinæ composita, compound tincture of savin.

Take of savin extract one ounce; tincture of castor one pound; tincture of myrrh half a pound. Digest until the savin is dissolved, and strain.

Dose half a drachm to one drachm.

Tinctura scillæ, tincture of squill.

Take of recently dried squill four ounces; proof spirit two pounds. Digest for eight days, and pour off the liquor.

Dose from twenty drops to a drachm.

Tinctura valerianæ, tincture of valerian.

Take of wild valerian, powdered coarsely, four ounces; proof spirit two pounds. Digest with a gentle heat for eight days, and strain.

Tinctura valerianæ ammoniata, ammoniated tincture of valerian.

Take of the coarse powder of wild valerian four ounces; compound spirit of ammonia two pounds. Digest for eight days, and strain.

Dose from one to two drachms.

Tinctura zinziberis, tincture of ginger.

Take of powdered ginger two ounces; proof spirit two pounds. Digest with a gentle heat for eight days, and strain.

Extracta, extracts.

1. Extraca per aquam, extracts by water.

Extractum gentianæ luteæ, extract of gentian, Ed. Ext. gent. Lond.

Take of gentian root any quantity; add to it, when cut and bruised, eight parts of distilled water. Boil it to half, and with strong pressure strain. Then evaporate the liquor to the consistence of thick honey by means of a bath of boiling water, saturated with muriat of soda.

In the same manner are prepared the following:

Extractum radicis glycyrrhizæ glabræ, extract of liquorice, Ed. Extr. glycyr. Lond.—Hellebori nigri, of hellebore, Ed. and Lond.—Foliorum rutæ graveolentis, of rue, Ed. Extr. rutæ, Lond.—Foliorum cassiæ sennæ, of senna, Ed. Extr. sennæ, Lond.——Florum anthemidis nobilis, of chamomile, Ed. Extr. cham. Lond.—Capitum papaveris somniferi, of poppy, Ed. Extr. pap. alb. Lond.—Ligni hæmatoxyli campechensis, of logwood, Ed. Extr. hæmatoxyli, Lond.

Besides these, in the London Ph. we have the following:

Extractum cacuminis genistæ, extract of broom tops. Sabinæ, of savin. Cinchonæ, of Peruvian bark; which last is ordered to be prepared as follows:

Take of Peruvian bark coarsely powdered one pound; distilled water twelve pounds. Boil for an hour or two, and pour off the liquor; which, while hot, will be red and pellucid, but as it cools becomes yellow and turbid. Pour on again the same quantity of water, boil as formerly, and repeat the boiling until the liquor, when cold, remains limpid. Then mix all the liquors (strained) together, and evaporate to a proper consistence. The extract should be prepared under two forms; one soft, fit to form pills; the other hard, so that it may be reduced to powder.

Dose fifteen grains.

2. Extracta per aquam et alcohol, extracts by water and alcohol.

Extractum cinchonæ officinalis, extract of Peruvian bark, Ed. Extract. cinchonæ, Lond.

Take of Peruvian bark in powder one pound; alcohol four pounds. Digest for four days, and pour off the tincture. Boil the residuum in five pounds of water for a quarter of an hour, and while hot strain through linen. Repeat this decoction and straining with the same quantity of water, and evaporate the liquor to the consistence of thick honey. Then mix the liquors thus inspissated, and reduce them to a proper consistence in a bath of boiling water, saturated with muriat of soda.

Dose ten or fifteen grains.

Extractum radicis convolvuli jalapæ, extract of jalap, Ed. Extract. jalapii, Lond.

To be prepared in the same manner as the last.

Dose ten or twelve grains.

Besides these the following extracts are peculiar to the London Ph.

Extractum cascarillæ, extract of cascarilla.

Dose twenty or thirty grains.

Extractum colocynthidis compositum, compound extract of colocynth.

Take of the pith of colocynth, cut small, six drachms; socotorine aloes powdered one ounce and a half; powdered scammony half an ounce; lesser cardamoms, freed from the husks, and powdered, one drachm; proof spirit one pound. Digest the colocynth with the spirit, with a gentle heat, for four days. To the expressed tincture add the scammony and aloes. These being dissolved, draw off the spirit by distilling; then evaporate the water, and add the seeds towards the end of the evaporation. Make an extract proper for forming pills.

A cathartic of considerable power. Dose from five grains to a scruple.

Opium purificatum, purified opium.

Take of opium, cut small, one pound; proof spirit twelve pounds. Digest with a gentle heat, and frequent agitation, until the opium is dissolved; strain the tincture through paper, and distil it to a proper consistence. Purified opium should be kept in two forms: soft, so as to be fit to make pills; and hard, so as to be capable of reduction to powder.

This is an unnecessary preparation.

Aquæ stillatitiæ, distilled waters.

Aqua distillata, distilled water, Ed. and Lond.

Let water be distilled in close vessels until about two-thirds have come over.

Aqua corticis citri aurantii, water of orange-peel.

Take of fresh orange-peel two pounds; pour on these as much water, that when ten pounds shall have been drawn off a sufficient quantity shall remain to prevent empyreuma. After due maceration, let ten pounds be distilled.

In the same manner prepare the following, ten pounds of water being drawn off from each of the annexed quantities:

Aqua corticis fructus citri medicæ recentis, fresh lemon-peel water (with two pounds).

—— corticis lauri cassiæ, cassia water (with one pound).

Aqua corticis lauri cinnamomi, cinnamon water. Aq. cinnamomi, Lond. (with one pound).

—— menthæ piperitæ florentis, peppermint water (with three pounds). Aq. menthæ piperitidis, Lond.

—— menthæ pulegii florentis, pennyroyal water (with three pounds). Aq. pulegii, Lond.

—— fructus myrti pimentæ, pimento water (with half a pound). Aq. pimento, Lond.

—— petalorum rosæ centifoliæ recentium, rose water (with six pounds). Aq. rosæ, Lond.

Besides these we have in the Ph. Lond. Aqua anethi, dill seed water.—Aqua fœniculi, fennel seed water.—Aqua menthæ sativæ, spearmint water. To each pound of distilled water let half an ounce be added of diluted alcohol.

Spiritus stillatitii, distilled spirits.

Spiritus carui, spirit of caraway, Ed. Sp. carui, Lond.

Take of caraway seeds half a pound; pour on them nine pounds of diluted alcohol. Macerate in a closed vessel for two days; then add as much water as is required to prevent empyreuma; and distil over nine pounds.

In the same manner are to be prepared the following spirits, nine pounds being drawn from the quantities affixed to each.

Spiritus corticis lauri cinnamomi, cinnamon spirit (with one pound). Sp. cin. Lond.

—— menthæ piperitæ florentis, spirit of peppermint (with one pound and a half). Sp. menth. p. Lond.

—— nucis myristicæ moschatæ, nutmeg spirit (with two ounces). Spirit. nuc. mosch. Lond.

—— fructus myrti pimentæ, pimento spirit (with half a pound). Sp. pimento, Lond.

In the Lond. Ph. the following are added: Spiritus menthæ sativæ, —— of spearmint. Sp. pulegii, —— of pennyroyal.

The following are the compound spirits of the Pharmacopœias:

Spiritus juniperi communis compositus, compound spirit of juniper, Ed. Sp. junip. comp. Lond.

Take of bruised juniper berries one pound; caraway seeds, fennel seeds, of each one ounce and a half; diluted alcohol nine pounds. Macerate for two days, and adding water sufficient to prevent empyreuma, draw over nine pounds.

Spiritus anisi compositus, compound spirit of anise, Ph. Lond.

Take of anise and of angelica seeds, of each bruised half a pound; proof spirit one gallon; water sufficient to prevent empyreuma. Distil one gallon.

Spiritus raphani compositus, spirit of horse-radish, Lond.

Take of fresh horse-radish root, dried orange-peel, of each two pounds; fresh garden scurvy-grass four pounds; bruised nutmegs one ounce; proof spirit two gallons; water sufficient to prevent empyreuma. Distil over two gallons.

The following are distilled with pure alcohol:

Spiritus lavendulæ spicæ compositus, compound spirit of lavender, Ed. Sp. lavend. comp. Lond.

Take of spirit of lavender (which is prepared with two pounds of lavender flowers, and eight pounds of alcohol, seven pounds being distilled over in a water-bath) three pounds; spirit of rosemary one pound; cinnamon one ounce; cloves two drachms; nutmeg half an ounce; red saunders wood three drachms. Macerate for seven days, and strain.

Spiritus rorismarini officinalis, spirit of rosemary, Ed. Sp. rorism. Lond.

Take of fresh rosemary tops two pounds; alcohol eight pounds. Draw off seven pounds by distilling in a water-bath.

Alcohol. In the London Ph. the following process is ordered for its preparation:

Take of rectified spirit of wine one gallon; prepared kali hot one ounce. Mix the spirit with the pure kali, and then add one pound of the prepared kali while hot; agitate and digest for twenty-four hours. Pour off the spirit; now add the remainder of the prepared kali, and distil from a water-bath. The alcohol is to be kept in a closely stopped vessel. The prepared kali should be heated to 300°. The specific gravity of alcohol to distilled water is as 815 to 1000.

Olea volatilia, volatile, or essential, oils.

Olea herbæ menthæ piperitæ florentis, oil of peppermint, Ed. Ol. menth. p. Lond.

—— herbæ juniperi sabinæ, — of savin, Ed.

—— summitarum florentum rorismarini officinalis, — of rosemary, Ed. Ol. rorism. Lond.

—— spicarum lavendulæ florentium spicæ, — of lavender, Ed. Ol. lav. Lond.

—— seminum pimpinellæ anisi, — of anise, Ed. Ol. ess. anisi, Lond.

—— baccarum juniperi communis, — of juniper, Ed. Ol. junip. Lond.

—— radicis lauri sassafras, — of sassafras, Ed. Ol. rad. sassaf. Lond.

—— fructus myrtæ pimentæ, — of pimento, Ed.

—— essentiale carui, — of caraway, Lond.

—— menthæ sativæ, — of spearmint, Lond.

—— origani, of wild thyme, Lond.

—— pulegii, of pennyroyal, Lond.

These oils are to be prepared in the same manner as distilled waters, except that a smaller quantity is to be added of water. Seeds or roots are to be bruised or rasped. The oil comes over with the water; and according as it is lighter or heavier, it swims on the surface, or falls to the bottom. It is afterwards to be separated.

Oleum succini et acidum succinicum, oil and acid of amber, Ed. Sal et ol. suc. Lond.

Take of amber in powder, and pure sand, of each equal parts; place them mixed in a glass retort, of which they shall fill one-half. Having adapted a large receiver, distil from a sand-bath, with a gradually raised fire. First will come over a watery liquor with a little yellow oil; then yellow oil with an acid salt; afterwards a reddish and black oil. Let the liquor be poured out of the receiver, and the oil separated from the water. Let the acid salt, collected from the sides of the receiver and from the neck of the retort, be pressed between folds of bibulous paper, and freed from the adhering oil. Then let it be purified by solution in hot water and crystallization.

Oleum succini purissimum, purified oil of amber, Ed. Ol. succ. rectific. Lond.

Distil oil of amber, mixed with water, six times its quantity, from a glass retort, until two-thirds have passed over into the receiver. Then separate the oil from the water, and preserve it in vessels effectually stopped.

Oleum terebinthinæ volatile purissimum, rectified oil of turpentine, Ed. Ol. tereb. rect. Lond.

Take of volatile oil of turpentine one pound; water four pounds. Distil as long as any oil passes over.

Oleum animale, animal oil, Lond.

Take of oil of hartshorn one pound. Distil three times

Oleum petrolei, oil of mineral tar, Lond.

Distil petroleum in a sand-bath.

Oleosa, oily preparations.

Oleum ammoniatum, ammoniated oil.

Take of olive oil two ounces; water of ammonia two drachms. Mix them.

The linimentum ammoniæ fortius of the London Ph. is prepared with water of pure ammonia one ounce: olive oil two ounces.

The linim. ammoniæ, Ph. Lond. is made with water of carbonated ammonia half an ounce; olive oil an ounce and a half.

These are all used as rubefacients.

Oleum lini cum calce, linseed oil with lime.

Take of linseed oil and lime water, of each equal parts. Mix them.

An application to burns.

Oleum camphoratum, camphorated oil.

Take of olive oil two ounces; camphor half an ounce. Mix so as to dissolve the camphor.

An anodyne and stimulant embrocation.

Oleum sulphuratum, sulphurated oil, Ed. Ol. sulph. Lond.

Take of olive oil eight ounces; sublimed sulphur one ounce. Boil with a slow fire in a large iron pot, stirring constantly, till they unite.

This preparation is discarded from practice.

In the London Pharmacopœia a solution of oil in petroleum, petroleum sulphuratum, is ordered to be made.

Sales et salina, salts and saline preparations.

Acidum acetosum distillatum, distilled acetous acid, Ed. Acetum distill. Lond.

Distil eight pounds of acetous acid in glass vessels with a slow fire. The first two pounds that come over are to be thrown away as too watery; the four pounds which follow are the distilled vinegar; the residuum gives a still stronger, but a too much burnt acid.

Acidum acetosum forte, strong acetous acid.

Take of dried sulphate of iron one pound; acetite of lead ten ounces. Rub them together. Place them in a retort, and distil from sand, with a moderate fire, as long as acid is produced.

Acidum acetosum, acetous acid, Lond.
Take of verdigris, in coarse powder, two pounds; dry it perfectly in a bath of water saturated with sea salt. Then distil in a sand-bath, and distil the liquor a second time. Its specific gravity is as 1050 to 1000.

Acidum benzoicum, benzoic acid, Ed. Flores benzoes, Lond.
Take of benzoin, in powder, any quantity. Place it in an earthen pot, to the mouth of which has been adapted a paper cone; apply a gentle fire, that the acid may be sublimed: if it is contaminated with oil, it is to be purified by solution in hot water and crystallization, or, as the Ph. Lond. directs, by mixing it with white clay, and again subliming.

Acidum muriaticum, muriatic acid, Ed. Acid. muriat. Lond.
Take of muriat of soda two pounds; sulphuric acid sixteen ounces; water one pound. First expose the muriat of soda in a pot to a red heat for a short time; when cold put it into a retort. Then pour the acid mixed with the water and cold on the muriat of soda. Distil from a sand-bath, with a gentle heat, as long as acid comes over. Its specific gravity is as 1170 to 1000.

Acidum nitrosum, nitrous acid, Ed. and Lond.
Take of pure nitrat of potass powdered two pounds; sulphuric acid sixteen ounces; the nitrat of potass being put into a glass retort, pour upon it the sulphuric acid, and distil from a sand-bath, with a fire gradually raised, until the iron pot is of an obscure red heat. Its specific gravity is 1550 to 1000.

Acidum nitrosum dilutum, diluted nitrous acid, Ed. and Lond.
Take of nitrous acid, water, equal weights. Mix them, avoiding the noxious vapours.

Acidum nitricum, nitric acid.
Take of nitrous acid any quantity; put it into a retort; and having adapted a receiver, apply a very gentle heat, until the reddest part shall have passed over, and the acid remaining in the retort shall have become nitric.

Spiritus ætheris nitrosi, spirit of nitrous ether, Ed. and Lond.
Take of alcohol three pounds; nitrous acid one pound; pour the alcohol into a large phial, placed in a vessel filled with cold water, and add the acid gradually with constant agitation. Close lightly the phial, and set it aside for seven days in a cool place; then distil the liquor with the heat of boiling water into a receiver cooled with water or snow, as long as any spirit shall pass over.

Dose from thirty to fifty drops.

Acidum sulphuricum dilutum, diluted sulphuric acid, Ed. Acid vitriolicum dilut. Lond.
Take of sulphuric acid one part; water seven parts (in the Ph. Lond. eight). Mix them.

Dose from fifteen to thirty drops.

Acidum sulphuricum aromaticum, aromatic sulphuric acid.
Take of alcohol two pounds; sulphuric acid six ounces. Drop gradually the alcohol upon the acid. Digest the mixture with a very gentle heat for three days in a close vessel; then add cinnamon an ounce and a half; ginger one ounce. Digest again in a closed vessel for six days, and filtre through paper with a glass funnel.

Dose about thirty drops.

Æther sulphuricus, sulphuric ether, Ed. Æth. vitriolicus, Lond.
Take of sulphuric acid, alcohol, of each thirty-two ounces; pour the alcohol into a glass retort, capable of bearing a sudden heat; then pour on the acid in a continued stream. Mix gradually with frequent and gentle agitation; then immediately distil from a sand-bath, heated previously, into a receiver kept cool by water or snow. The fire is to be so regulated, that the liquor may be made to boil as soon as possible, and continue to boil until sixteen ounces have distilled over; then remove the retort from the sand. To the distilled liquor add two drachms of potass; then again distil from a high-necked retort, with a very gentle heat, into a receiver preserved cool, until ten ounces have come over. If after the first distillation sixteen ounces of alcohol are added to the acid remaining in the retort, and the distillation is repeated, ether will again be produced; and this process may be repeated more than once.

Dose from thirty to sixty drops.

Æther sulphuricus cum alcohole, sulphuric ether with alcohol.
Take of sulphuric ether one part; alcohol two parts. Mix them.

The London college order a compound spirit (sp. ætheris vitriolici comp.) to be prepared by mixing two pounds of unrectified ether with three drachms of oil of wine.

Æther sulphuricus cum alcohole aromaticus, aromatic sulphuric ether with alcohol.
This is made from the same materials and in the same manner with the compound tincture of cinnamon, unless that sulphuric ether with alcohol is employed instead of diluted alcohol.

These are useless preparations.

Carbonas ammoniæ, carbonat of ammonia, Ed. Ammonia preparata, Lond.
Take of muriat of ammonia one pound; carbonat of lime, vulgarly called chalk, dried, two pounds. Being each separately powdered, mix them, and sublime from a retort into a receiver kept cold.

Dose from five grains to a scruple.

Aqua carbonatis ammoniæ, water of carbonat of ammonia, Ed. Aq. ammoniæ, Lond.
Take of muriat of ammonia, carbonat of potass, of each sixteen ounces; water two pounds. To the salts mixed and put into a glass retort pour on the water; then distil to dryness from a sand-bath, with a fire gently raised.

Liquor volatilis, sal, et oleum cornu cervi, volatile liquor, salt, and oil of hartshorn, Lond.
Take of hartshorn ten pounds; distil, gradually increasing the fire. A volatile liquor, salt, and oil, come over. The oil and the salt being separated, distil the liquor three times. To the salt add an equal weight of prepared chalk, and sublime three times, or until it becomes white. The same volatile liquor, salt, and oil, may be procured from any of the parts of animals, except fat.

Aqua ammoniæ, water of ammonia, Ed. Aqua ammoniæ puræ, Lond.
Take of muriat of ammonia sixteen ounces; lime fresh-prepared two pounds; water six pounds. To one pound of water, in an iron or an earthen vessel, add the lime broken down, and close the vessel for twenty-four hours, until the lime falls into powder, which is to be put into a retort. To this add the muriat of ammonia dissolved in five pounds of water, and, shutting the mouth of the retort, mix them with agitation. Lastly, distil with such a moderate heat, that the operator can easily apply his hand to the retort into a receiver kept cold, until twenty ounces have distilled over. In this process the vessels are to be so luted, as that the penetrating vapours may be effectually confined.

Dose about twenty drops internally; outwardly it is used as a rubefacient.

Alcohol ammoniatum, ammoniated alcohol, Ed. Sp. ammoniæ, Lond.
Take of diluted alcohol four pounds; muriat of ammonia four ounces; carbonat of potass six ounces. Mix, and draw off two pounds by distilling with a gentle fire.

Alcohol ammoniatum aromaticum, aromatic ammoniated alcohol, Ed. Sp. amm. comp. Lond.
Take of spirit of ammonia eight ounces; volatile oil of rosemary a drachm and a half; volatile oil of lemon one drachm. Mix so as to dissolve the oils. In the Ph. Lond. oil of cloves is ordered instead of the rosemary oil.

Dose from twenty to forty drops.

Alcohol ammoniatum fœtidum, fœtid ammoniated alcohol, Ed. Sp. ammoniæ fœtidæ, Lond.
Take of spirit of ammonia eight ounces; assafœtida half an ounce. Let them be digested in a close vessel for twelve hours; then bring over eight ounces by the heat of a water-bath.

Dose thirty or forty drops.

Spiritus ammoniæ succinatus, Ph. Lond. Succinated spirit of ammonia.
Take of alcohol one ounce; water of pure ammonia four ounces; rectified oil of amber one scruple; soap ten grains. Digest the soap and the oil of amber in the alcohol until they are dissolved; then add the water of pure ammonia, and mix by agitation.

This has been named eau de luce.

Carbonas potassæ, carbonat of potass, Ed. Kali præparatum, Lond.
Let impure carbonat of potass (pearl-ashes) be put into a crucible, and brought to a red heat, that the oily impurities, if there are any present, may be burnt out; then rubbing the carbonat with an equal weight of water, let them be well mixed by agitation. The liquor, after the impurities have subsided, being poured off into a clean iron pot, is to be boiled to dryness; towards the end of the boiling the salt is to be kept constantly stirred, lest any adhere to the vessel.

In the London college this preparation is better ordered by dissolving the pearl-ashes, and evaporating the solution till a pellicle appears on the surface; then immediately setting it aside, previous to further evaporation, that the sulphat and muriat of potass, which the pearl-ashes contain, may be separated by crystallization.

Carbonas potassæ purissimus, pure carbonat of potass (salt of tartar).

Take of impure supertartite of potass any quantity. Having wrapped it in moist bibulous paper, or put it into a crucible, place it among live coals, that it may be burnt into a black mass. Being reduced to powder, subject it to a moderate heat in an open crucible, until it becomes white, or cinder-like, taking care that it does not melt. Then let it be dissolved in warm water, the liquor strained through linen, and evaporated in a clean iron vessel, stirring the matter assiduously towards the end of the evaporation with an iron spoon, that it may not adhere to the bottom of the vessel. A very white salt will remain, which is to be left for some time on the fire, until the bottom of the vessel is nearly of a red heat. When cold, the salt is to be preserved in a glass vessel well stopped.

Aqua potassæ, water of potass, Ed. Aqua kali puri, Lond.

Take of newly prepared lime eight ounces; carbonat of potass six ounces. Put the lime into an iron or earthen vessel, with twenty-eight ounces of warm water. The ebullition being over, immediately add the salt; and the whole being completely mixed, close the vessel until they become cold. Now let them be well agitated, and poured into a glass funnel, the throat of which is obstructed with clean linen. Cover the upper orifice of the funnel while its neck is inserted in another glass vessel, that the water of potass may gradually drop through the linen into the lower vessel. When it first ceases to drop, pour into the funnel some ounces of water, cautiously, that it may swim above the matter. The water of potass will now again begin to drop. In this manner is to be repeated the affusion of water until three pounds have been filtred, which will be in the space of two or three days. The upper are to be mixed by agitation with the lower parts of the liquor, which is to be kept in a well stopped vessel.

Aqua supercarbonatis potassæ, water of supercarbonat of potass.

Take of water ten pounds; pure carbonat of potass one ounce. Dissolve, and expose the solution to a stream of carbonic acid gas, which is produced from carbonat of lime, sulphuric acid, of each three ounces, with three pounds of water cautiously and gradually mixed. The apparatus invented by Dr. Nooth is well adapted to this preparation. If a greater quantity is required, Woulfe's apparatus is to be preferred. In proportion to the coldness of the air, and the extent of pressure, the liquor will be better. It should be kept in well stopped vessels.

Carbonas sodæ, carbonat of soda, Ed. Natron præparatum, Lond.

Take of impure carbonat of soda any quantity; bruise it, and boil it in water until all the salt is dissolved. Strain the solution through paper, and evaporate it in an iron vessel, that, after cooling, crystals may form.

The barilla of commerce.

Aqua supercarbonatis sodæ, water of supercarbonat of soda.

This is prepared from ten pounds of water, and two ounces of carbonat of soda, in the same mode as the supercarbonat of potass.

Aqua acetitis ammoniæ, water of acetite of ammonia, Ed. Aq. ammoniæ acetatæ, Lond.

Take of carbonat of ammonia any quantity. Pour on it as much distilled acetous acid as may be necessary exactly to saturate the ammonia.

Acetis potassæ, acetite of potass, Ed. Kali acetatum, Lond.

Take of pure carbonat of potass any quantity. Boil it with a gentle heat in four or five times its weight of distilled acetous acid, and at different times add more acid, until on the watery part of the former portion being nearly evaporated, the acid newly added occasions no effervescence. This will be the case when about twenty parts of acid have been consumed. Then let it be slowly dried. Let the remaining impure salt be liquefied with a gentle heat for a short time; then dissolved in water, and strained through paper. If the liquefaction has been properly done, the strained liquor will be limpid; if not, it will be of a brown colour. Afterwards evaporate this liquor with a gentle heat in a shallow glass vessel, well closed, that it may not liquefy by the air.

Potassa, potass, Ed. Kali purum, Lond.

Take of water of potass any quantity; evaporate it in a covered clean vessel of iron, until, the ebullition being finished, the saline matter flows smoothly like oil, which will be the case before the vessel is at a red heat. Then pour it on a clean iron plate; cut it into small masses before it becomes hard, and immediately put them into a phial well stopped.

Potassa cum calce, potass with lime, Ed. Calx cum kali puro, Lond.

Take of water of potass any quantity. Evaporate to one-third in a covered iron vessel; then mix with it as much newly slaked lime as may suffice to give it the consistence of a solid paste, which is to be kept in a stopt vessel.

Sulphas potassæ, sulphat of potass, Ed. Kali vitriolatum, Lond.

Take of sulphuric acid, diluted with six times its weight of water, any quantity; put it into a large glass vessel; and gradually drop into it of carbonat of potass, dissolved in six times its weight of water, as much as may suffice perfectly to saturate the acid. The effervescence being finished, filtre the liquor through paper; and, after due exhalation, put it aside that crystals may form. This salt may otherwise be made by dissolving the residuum of the distillation of nitrous acid in warm water, and saturating it with carbonat of potass.

Sulphas potassæ cum sulphure, sulphat of potass with sulphur.

Take of nitrat of potass in powder, sublimed sulphur, equal weights. Throw them well mixed into a red-hot crucible, by small quantities at a time. The deflagration being over, let the salt cool. Keep it in a glass phial well stopped.

Tartris potassæ, tartrite of potass, Ed. Kali tartarisatum, Lond.

Take of carbonat of potass one pound: supertartrite of potass three pounds, or as much as necessary; boiling water fifteen pounds. To the carbonat of potass dissolved in the water add gradually the supertartrite of potass rubbed to fine powder, as long as effervescence is excited, which generally ceases before three times its weight of carbonat of potass have been thrown in. When the liquor is cold filtre it through paper, and set it aside, that crystals may be formed.

Dose as a purgative one ounce.

Tartris potassæ et sodæ, tartrite of potass and soda, Ed. Natron tartarisatum, Lond.

This is to be prepared from carbonat of soda and supertartrite of potass, in the same mode as tartrite of potass.

A pleasant purgative. Dose an ounce.

Phosphas sodæ, phosphat of sodæ.

Take of bones burnt to whiteness and powdered ten pounds; sulphuric acid six pounds; water nine pounds. Mix the powder with the acid in an earthen vessel; then add the water, and again mix. Keep the vessel in a water-bath for three days; then dilute the matter, by adding nine pounds more of boiling water, and strain through a strong linen cloth, pouring gradually over it boiling water, until all the acid is washed out. Put aside the strained liquor that the impurities may subside, from which pour it off, and evaporate to nine pounds. To this liquor, again poured off from its impurities, and heated in an earthen vessel, add carbonat of soda dissolved in warm water, till it no longer excites effervescence. Now strain, and put it aside, that crystals may form. These being removed, add, if necessary, to the liquor, a little carbonat of soda, that the phosphoric acid may be completely saturated, and again prepare it by evaporation to form crystals as long as these can be produced. Lastly, let the crystals be preserved in a vessel well stopt.

A mild and useful cathartic. Dose one ounce.

Sulphas sodæ, sulphat of soda, Ed. Natron vitriolatum, Lond. (Glauber's salt.)

Dissolve the acidulous salt, which remains after the distillation of muriatic acid, in water, and add to it chalk, in order to remove the superfluous acid. Put it aside until its impurities have subsided; then having poured off the liquor, and strained it through paper, reduce it by evaporation, so as to form crystals.

Dose one ounce, or more.

Sulphuretum potassæ, sulphuret of potass, Ed. Kali sulphuratum, Lond.

Take of carbonat of potass, sublimed sulphur, of each eight ounces; having rubbed them together, let them be put into a large coated crucible, to which a cover being adapted, apply the fire cautiously, until the materials melt The crucible, when it has cooled, is to be broken, and the sulphuret taken out, and preserved in a close-stopt phial.

Hydro-sulphuretum ammoniæ, hydro-sulphuret of ammonia.

Take of water of ammonia four ounces. Expose it in a chemical apparatus to the stream of gas which arises from sulphuret of iron four ounces, muriatic acid eight ounces, previously diluted with two pounds and a half of water. The sulphuret of iron for this purpose is conveniently prepared from three parts of purified iron filings, and one of sublimed sulphur, mixed, and exposed in a covered crucible to a moderate fire until they unite.

This is principally given in diabetes, in the dose of four or five drops.

Murias barytæ, muriat of barytes.

Take of sulphat of barytes two pounds; powdered charcoal four ounces. Roast the sulphat that it may be more easily powdered fine; then mix the charcoal; put the matter into a crucible, to which adapt a cover, and apply a vigorous fire for some hours. Put the matter well rubbed into six pounds of boiling water, in a closed glass or earthen vessel, and mix them by agitation, guarding as much as possible against the access of air. Let the vessel stand in a water-bath until the undissolved matter has subsided; then pour off the liquor. Pour four pounds of boiling water on the residuum, which add to the former liquor after agitation and subsidence. While it is still hot (or, if it has cooled, after it has been heated), drop into it muriatic acid as long as effervescence is occasioned. Then strain and evaporate it so as to form chrystals.

Solutio muriatis barytæ, solution of muriat of barytes.

Take of muriat of barytes one part; distilled water three parts. Dissolve.

Dr. Crawford introduced this in scrophulous affections. Dose from five to twenty drops.

Solutio muriatis calcis, solution of muriat of lime.

Take of pure carbonat of lime (white marble) bruised into small pieces nine ounces; muriatic acid sixteen ounces; water eight ounces. Mix the acid with the water, and gradually add the pieces of carbonat of lime: the effervescence being over, digest for an hour. Pour off the liquor, and evaporate to dryness. Dissolve the residuum in its weight and a half of water, and strain.

This has been recently introduced as a tonic. Dose thirty drops.

Carbonas magnesiæ, carbonat of magnesia, Ed. Magnesia alba, Lond.

Take of sulphat of magnesia, carbonat of potass, of each equal weights. Let them be separately dissolved in twice their weight of warm wrter, and either strained or otherwise freed from impurities; then mix them, and add eight times their weight of boiling water. Boil the liquor a little, and stir it during the boiling; then allow it to rest until the heat is in some measure diminished; then strain through linen, upon which the salt will remain. Let it be washed with pure water until it is perfectly tasteless.

Magnesia, magnesia, Ed. Magnesia usta, Lond.

Let carbonat of magnesia be exposed in a crucible to a red heat for two hours; then let it be preserved in glass vessels well stopped.

Metallica, metallic preparations.

Nitras argenti, nitrat of silver, Ed. Argentum nitratum, Lond.

Take of the purest silver, extended in plates and cut, four ounces; diluted nitrous acid eight ounces; distilled water four ounces. Dissolve the silver with a gentle heat in a phial, and evaporate the solution to dryness. Then put the mass into a large crucible, which is to be placed on the fire, at first gentle, and gradually increased, until the mass flows like oil. Then pour it into iron pipes, warmed and rubbed with grease. Keep it in a glass vessel well stopt.

A strong, and frequently employed, caustic.

Sulphuretum antimonii, prepared or sulphureted antimony, Ed. Antim. præparatum, Lond.

This is to be prepared in the same manner as carbonat of lime.

Oxidum antimonii cum sulphure vitrificatum, vitrified sulphureted oxide of antimony, Ed. Antim. vitrificatum, Lond.

Strew sulphuret of antimony coarsely powdered like sand on a shallow earthen vessel not glazed, and apply to it a moderate fire that the sulphuret of antimony may be slowly heated; at the same time stir the powder constantly, that it may not run into lumps. White vapours arise, smelling like sulphur. When these, while the same degree of heat is kept up, cease, augment the heat in some measure, that vapours may again exhale. Proceed in this manner until the powder, now raised to a red heat, gives out no more vapours. This powder being put into a crucible, is to be melted with a strong fire, until it assumes the appearance of fused glass. It is now to be poured upon a heated brass plate.

Oxidum antimonii vitrificatum cum cera, vitrified oxide of antimony with wax.

Take of yellow wax one pound; vitrified sulphureted oxide of antimony eight parts. To the wax melted in an iron vessel, add the oxide reduced to powder, and roast with a gentle fire for a quarter of an hour, constantly stirring with a spatula; then pour off the matter, which when cold is to be powdered.

This is an obsolete remedy.

Oxidum antimonii cum phosphate calcis, oxide of antimony with phosphat of lime, Ed. Pulvis antimonialis, Lond.

Take of sulphuret of antimony coarsely powdered, hartshorn shavings, of each equal parts. Mix and throw them into a wide iron pot red-hot, and keep them constantly stirred until they are burnt into a cineritious-coloured matter, which is to be removed from the fire, rubbed into a powder, and put into a coated crucible. To this crucible, lute another inverted, in the bottom of which is drilled a small hole; apply the fire, which is to be gradually raised to a white heat, and kept so for two hours. Lastly, rub the matter when cold into a very fine powder.

This preparation is nearly the same as James's powder. Dose five or six grains.

Sulphuretum antimonii præcipitatum, precipitated sulphuret of antimony, Ed. Sulphur antimonii præcipitatum, Lond.

Take of water of potass four pounds; water three pounds; prepared sulphuret of antimony two pounds. Boil them in a covered iron pot on a gentle fire for three hours, stirring frequently with an iron spatula, and adding water occasionally. Strain the liquor while hot through a doubled linen cloth, and to the strained liquor add as much as may be necessary to precipitate the sulphuret, which carefully wash with warm water.

A precipitate nearly similar to this has been much employed on the continent, especially under the name of kermes mineral. Both the one and the other have been principally used as alterative or diaphoretic. Their operation is uncertain. Dose five or six grains.

Oxidum antimonii cum sulphure per nitratum potassæ, oxide of antimony with sulphur and nitrat of potass, Ed. Crocus antimonii, Lond.

Take of sulphuret of antimony, nitrat of potass, of each equal weights. Triturate them separately; and having mixed them well together, throw them into a red-hot crucible. The deflagration being finished, separate the reddish matter from the white crust, and rub it into powder, which is to be frequently washed with warm water until it becomes tasteless.

This is used in some of the other preparations; but as a medicine it is so uncertain in its operation, that it is scarcely employed.

Antimonium muriatum, muriat of antimony, Ed. and Lond.

Take of oxide of antimony with sulphur, nitrat of potass, sulphuric acid, of each one pound; dried muriat of soda, two pounds. Pour the acid into a retort, adding by degrees the muriat of soda, and the oxide of antimony previously mixed. Then distil from warm sand. Expose the distilled matter for some days to the air, that it may liquefy; then pour the liquid from the impurities.

This preparation is not proper for internal administration.

Tartris antimonii, tartrite of antimony (tartar emetic), Ed. Antimonium tartarisatum, Lond.

Take of oxide of antimony with sulphur by nitrat of potass three parts; supertartrite of potass four parts; distilled water thirty-two parts. Boil them in a glass vessel for a quarter of an hour; strain the liquor through paper, and set it aside that it may form crystals.

The most certain and useful of all antimonial preparations. Dose, as an emetic, from one to two or more grains; as a diaphoretic, a quarter of a grain.

Vinum tartritis antimonii, wine of tartrite of antimony.

Take of tartrite of antimony twenty-four grains; white wine one pound. Mix so as to dissolve the tartrite.

Vinum antimonii tartarisati, Ph. L. Wine of tartarised antimony.

Take of tartarised antimony two scruples; boiling distilled water by measure two ounces; Spanish white wine eight ounces. Dissolve the tartarised antimony in the boiling distilled water, and add the wine.

The two last preparations materially

differ in strength. Dose, as a diaphoretic, of the former about 40, of the latter 20, drops.

Vinum antimonii, antimonial wine, Ph. L.
Take of vitrified antimony powdered one ounce; Spanish white wine one pound and a half. Digest for twelve days with frequent agitation, and filtre through paper.

This is a preparation of very uncertain strength.

Antimonium calcinatum, calcined antimony, Ph. L. White oxide of antimony.
Take of antimony in powder eight ounces; powdered nitre two pounds. Mix them, and throw the mixture gradually into a red-hot crucible. Burn the matter which remains after the deflagration for half an hour, and when cold rub it to powder; then wash it with distilled water.

This has been employed as a substitute for James's powder. Its dose is however uncertain.

Ammoniaretum cupri, ammoniaret of copper (cuprum ammoniacum).
Take of pure sulphat of copper two parts; carbonat of ammonia three parts. Rub them assiduously in a glass mortar until all effervescence is over, and they form into a violet-coloured mass, which being wrapped in bibulous paper, is to be dried first on a chalkstone and afterwards by means of a gentle heat. The ammoniaret is to be preserved in a glass phial well stopped.

Dose half a grain at first, gradually increased to three or more grains.

Solutio sulphatis cupri composita, compound solution of sulphat of copper.
Take of sulphat of copper and sulphat of alumen, of each three ounces; water two pounds; sulphuric acid one ounce and a half. Boil the sulphats in water, that they may dissolve; then to the liquor filtred through water add the acid.

Aqua cupri ammoniati, water of ammoniated copper, Lond.
Take of sal ammoniac (muriat of ammonia) one drachm; lime-water one pound. Allow them to remain in a copper vessel until the ammonia is saturated with copper.

This is employed as a gentle escharotic.

Carbonas ferri præcipitatus, precipitated carbonat of iron.
Take of sulphat of iron four ounces; carbonat of soda five ounces; water ten pounds. Dissolve the sulphat in the water; then add the carbonat, previously dissolved in a quantity of water, as much as necessary, and mix them well together. Let the carbonat of iron which is precipitated be washed with warm water and afterwards dried.

Dr. Griffiths's preparation of steel is an extemporaneous formula similar to the above.

Sulphas ferri, sulphat of iron, Ed. Ferrum vitriolatum, Lond.
Take of purified filings of iron six ounces; sulphuric acid eight ounces; water two pounds and a half. Mix them; and the effervescence being finished, digest for a short time in a sand-bath. Then strain the liquor through paper, and after proper evaporation put it on one side in order to form crystals.

This is perhaps the most active and useful of the chalybeates. Dose from one to four or five grains.

Sulphas ferri exsiccatus, dried sulphat of iron.
Take of sulphat of iron any quantity: heat it in an earthen vessel unglazed on a gentle fire until it becomes white and perfectly dry.

Oxidum ferri rubrum, red oxide of iron.
Let dried sulphat of iron be exposed to a violent heat until it is converted into a red matter.

Tinctura muriatis ferri, tincture of muriat of iron, Ed. Tinctura ferri muriati, Lond.
Take of the purified black oxide of iron powdered three ounces; muriatic acid about ten ounces, or sufficient to dissolve the powder. Digest with a gentle heat, and the powder being dissolved, add sufficient quantity of alcohol to make the whole liquor two pounds and a half.

An active and useful preparation. Dose from ten to twenty drops.

Murias ammoniæ et ferri, muriat of ammonia and iron, Ed. Ferrum ammoniacale, Lond.
Take of red oxide of iron washed and again dried; muriat of ammonia, of each equal parts. Let them be well mixed, and sublime.

This preparation is not much in use.

Tinctura ferri ammoniacalis, Ph. Lond.
Take of ammoniacal iron four ounces; proof spirit by measure one pound. Digest and strain.

This is a superfluous preparation.

Ferrum tartarisatum, tartarised iron, Ph. Lond.
Take of filings of iron one pound; crystals of tartar powdered two pounds; distilled water one pound. Mix them, and expose the mixture to the air in an open glass vessel for eight days; then rub the matter dried by a sand-bath into a very fine powder.

Dose from five to ten or fifteen grains.

Vinum ferri, wine of iron, Ph. Lond.
Take of iron filings four ounces; Spanish white wine four pounds. Digest for a month with frequent agitation, and strain.

Dose one or two drachms.

Hydrargyrus purificatus, purified quicksilver, Ed. and Lond.
Take of quicksilver four parts; filings of iron one part. Rub them together, and distil from an iron vessel.

Acetis hydrargyri, acetite of quicksilver, Ed. Hydrargyrus acetatus, Lond.
Take of purified quicksilver three ounces; diluted nitrous acid four ounces and a half, or a little more than may suffice to dissolve the quicksilver; acetite of potass three ounces; boiling water eight pounds. Mix the quicksilver with the diluted nitrous acid, and towards the end of the effervescence digest, if it may be necessary, with a gentle heat, until the quicksilver is totally dissolved; then dissolve the acetite of potass in boiling water, and immediately on this solution while hot pour the other, mixing them by agitation. Then place the mixture on one side that crystals may form. These being put into a funnel, wash them with cold distilled water; and lastly dry them with a very gentle heat. In preparing the acetite of quicksilver, it is necessary that all the vessels and the funnel which are used, are of glass.

This has been employed as an antisyphilitic, in the dose of a grain night and morning. Its operation, however, is perhaps not to be depended on.

Murias hydrargyri, muriat of mercury, Ed. Hydrargyrus muriatus, Lond.
Take of purified quicksilver two pounds; sulphuric acid two pounds and a half; muriat of soda dried four pounds. Boil the quicksilver with the sulphuric acid in a glass vessel placed on a sand-bath till the matter becomes dry. When cold, mix it with the muriat of soda; then sublime it in a glass cucurbit, with a heat gradually raised. Separate the sublimed matter from the scoriæ.

This (the corrosive sublimate) is the most active of all the mercurial preparations. Dose about a fourth of a grain. It is not now so much as formerly used in the cure of syphilis.

Submurias hydrargyri, submuriat of quicksilver, Ed. Calomelas, Lond.
Take of muriat of quicksilver rubbed to powder in a glass mortar four ounces; purified quicksilver three ounces. Let them in a glass mortar be rubbed together, with a very little water, in order to guard against the acrid powder which would without this precaution arise, until the quicksilver is extinguished. Put the dried powder into an oblong phial, of which it shall occupy one-third, and let it be sublimed in a sand-bath. The sublimation being completed, and the phial broken, the red powder about the bottom and white about the neck of it, are to be both rejected, the remaining mass is again to be sublimed and rubbed into a fine powder, which is lastly to be washed with boiling distilled water.

This of all mercurial preparations is the most important in medicine. Its dose, according to the different diseases and circumstances under which it is employed, varies from an eighth of a grain to ten or more grains. It ought never to be given in solution.

Submurias hydrargyri præcipitatus, precipitated submuriat of mercury, Ed. Hydrargyrus muriatus mitis, Lond.
Take of diluted nitrous acid, purified quicksilver, of each eight ounces; muriat of soda four ounces and a half; boiling water eight pounds. Mix the quicksilver with the diluted acid, and towards the end of the effervescence digest with a gentle heat, frequently shaking the vessel. It is necessary that more quicksilver should be mixed with the acid than this can dissolve, that the solution may be obtained completely saturated. Dissolve at the same time the muriat of soda in the boiling water while it is warm; pour on it the other solution, and quickly mix them together. After the precipitation, pour off the saline liquor, and wash the submuriat of mercury by frequently adding warm water, pouring it off after each time of the subsiding of the precipitate until it comes off tasteless.

This preparation does not materially differ from the preceding.

Oxidum hydrargyri cinereum, ash-coloured oxide of quicksilver.

Take of purified quicksilver four parts; diluted nitrous acid five parts; distilled water fifteen parts; water of carbonat of ammonia as much as sufficient. Dissolve the quicksilver in the acid; add gradually the distilled water; then pour on as much of the water of carbonat of ammonia as will suffice to throw down the oxide of quicksilver, which is then to be washed with pure water and dried.

This has lately been recommended by Dr. Home and others as one of the most efficacious and permanent of antisyphilitic remedies. Dose one grain.

Oxidum hydrargyri rubrum per acidum nitricum, red oxide of quicksilver by nitrous acid, Ed. Hydrargyrus nitratus ruber, Lon.

Take of purified quicksilver one pound; of diluted nitrous acid sixteen ounces. Let the quicksilver be dissolved, and with a gentle fire evaporate the solution into a dry white mass, which rubbed into powder is to be put into a glass cucurbit, a thick glass plate being put over its surface; then having adapted a capital, and placed the vessel in sand, let it be roasted with a fire gradually raised until it assumes the form of small red scales.

This is used as an escharotic.

Subsulphas hydrargyri flavus, yellow subsulphat of quicksilver, Ed. Hydrargyrus vitriolatus, Lond.

Take of purified quicksilver four ounces; sulphuric acid six ounces. Put them into a glass cucurbit, and let them boil in a sand-bath to dryness; the white matter remaining at the bottom of the vessel being powdered, is to be thrown into boiling water; it will thus be changed into a yellow, which ought to be frequently washed with warm water.

This preparation, formerly denominated turpeth mineral, is scarcely at present employed in medicine.

Sulphuretum hydrargyri nigrum, black sulphuret of quicksilver, Ed. Hydrargyrus cum sulphure, Lond.

Take of purified quicksilver and sublimed sulphur, of each equal weights. Let them be rubbed together in a glass mortar with a glass pestle, until the globules of quicksilver entirely disappear.

This is vulgarly denominated ethiops mineral. It is the least active of all the mercurial preparations, and is not much in use.

The following additional preparations of mercury are found exclusively in the Ph. Lond.

Hydrargyrus sulphuratus ruber, red sulphureted quicksilver.

Take of purified quicksilver forty ounces; sulphur eight ounces. Mix the quicksilver with the melted sulphur. If the mixture inflames, extinguish it by covering the vessel. Powder and sublime the material.

This (cinnabar) is principally used to fumigate venereal ulcers.

Hydrargyrus cum creta, quicksilver with chalk.

Take of purified quicksilver three ounces; prepared chalk five ounces. Rub them together till the globules disappear.

This is scarcely employed.

Hydrargyrus calcinatus, calcined quicksilver.

Take of purified quicksilver one pound. Expose it in a glass cucurbit with a flat bottom, in a sand-bath, to a heat of 600°, until it concretes into a red powder.

This has been recommended in doses of half a grain or a grain in confirmed syphilis, which has appeared to oppose other mercurial preparations.

Calx hydrargyri albi, white calx of quicksilver.

Take of muriated quicksilver, sal ammoniac, water of prepared kali, of each half a pound. First dissolve the sal ammoniac, and then the muriated quicksilver, in distilled water, to which add the water of prepared kali. Wash the powder until it is tasteless.

White precipitate, as the above preparation is commonly called, is used externally in the form of ointment in psora, and other affections of the skin.

Acetis plumbi, acetate of lead, Ed. Cerussa acetata, Lond.

Take of white oxide of lead any quantity, put it into a cucurbit, and upon it pour twice its quantity in weight of distilled acetous acid; the mixture is to stand on warm sand, until the acid becomes sweet: then pour it off, and add a fresh quantity of acid as often as may be necessary, until it ceases to become sweet; then the whole liquor, freed from impurities, is to be evaporated to the consistence of thin honey, and put aside in a cool place that crystals may form, which are to be dried in the shade. Evaporate the remaining liquor so as to form new crystals, and repeat this process, till the liquor ceases to crystallize.

This preparation (the sugar of lead) is employed chiefly for injections and collyria.

Aqua lithargyri acetati, water of acetated litharge, Ph. Lond.

Take of litharge two pounds and four ounces; distilled vinegar one gallon. Mix them and boil to six pounds, stirring constantly; then put the liquor aside, and after the impurities have subsided, strain it.

This preparation has long been employed under the denomination of Goulard's extract. It is applied to the same purposes with the preceding.

Oxidum zinci, oxide of zinc.

Let a large crucible be placed in a furnace filled with burning coals, in such a manner that it shall be somewhat inclined to its mouth; and when the bottom of the crucible is at a moderate red heat, throw in pieces of zinc, each of them about the weight of a drachm. The zinc shortly inflames, and is converted into white flocculi, which from time to time are to be removed from the surface of the metal, with an iron spatula, that the combustion may be more effectual; when the inflammation ceases, remove the oxide of zinc from the crucible. Another piece being thrown in, renew the operation, which repeat as often as may be necessary. Lastly, let the oxide of zinc be prepared in the same manner as carbonat of lime.

Dose as a tonic, from 2 to 5 or more grains.

Sulphas zinci, sulphat of zinc. White vitriol.

Take of zinc, cut into small pieces, three ounces; sulphuric acid, five ounces; water, twenty ounces. Mix them, and the consequent effervescence being over, digest for some time on warm sand. Then strain through paper, and after due exhalation put the liquor aside, that chrystals may form.

This is often used as an injection and collyrium.

Solutio sulphatis zinci, solution of sulphat of zinc.

Take of sulphat of zinc sixteen grains, distilled water eight ounces, diluted sulphuric acid sixteen drops. Dissolve the sulphat of zinc in the water; then the acid being added, filtre through paper.

Aqua zinci vitriolati cum camphora, water of vitriolated zinc with camphor. Ph. Lond.

Take of vitriolated zinc half an ounce, camphorated spirit half an ounce by measure, boiling water by measure two pounds. Mix them, and filtre through paper.

This is used as a collyrium; it requires no further dilution.

Solutio acetitis zinci, solution of acetite of zinc.

Take of sulphat of zinc, one drachm; distilled water ten ounces. Dissolve it. Take then of acetite of lead, four scruples; distilled water, ten ounces; dissolve this. Mix the solutions; and when the liquor has remained some time at rest, strain it.

The solution is regarded as more astringent than the acetite of lead, and of a less irritating nature than the sulphat of zinc.

Pulveres, powders.

Pulvis aromaticus, aromatic powder. Ed. and Lond.

Take of cinnamon, smaller cardamom seeds, and ginger, of each equal parts. Rub them into a very fine powder, which is to be preserved in a glass phial well stopped. In the Ph. Lond. the proportion of cinnamon is greater, and one part is added of long pepper.

Pulvis asari Europæi compositus, compound powder of asarabacca, Ed. Pulv. asari compos. Lond.

Take of asarabacca leaves three parts; the leaves of marjoram and lavender flowers, of each one part. Rub them together to a powder.

A mild errhine.

Pulvis carbonatis calcis compositus, chalk powder.

Take of prepared carbonat of lime, four ounces; of cinnamon, a drachm and a half; nutmeg, half a drachm. Rub them together to powder.

Pulvis cretæ compositus, compound powder of chalk. Ph. Lond.

Take of prepared chalk, half a pound; cinnamon, four ounces; tormentil and gum arabic, of each three ounces; long pepper, half an ounce. Reduce them to powder separately, and then mix them.

Dose of either of the above aromatic astringents, from 15 grains to half a drachm.

Pulvis e creta compositus cum opio.

Take of compound powder of chalk, eight ounces; hard purified opium, rubbed to powder, one drachm and a half. Mix them.

Dose, one scruple, or half a drachm.

Pulvis chelarum cancri compositus, compound powder of crab's claws. Ph. Lond.
Take of prepared crab's claws one pound; prepared chalk, prepared coral, of each three ounces. Mix them.

This, though apparently a compound, is in reality a simple preparation, as the ingredients are all mere carbonats of lime.

Pulvis jalapæ compositus, compound powder of jalap.
Take of the powder of jalap one part; supertartrite of potass two parts; rub them together into a very fine powder.

This, in the dose of a drachm and a half, is an excellent cathartic.

Pulvis ipecacuanhæ et opii, powder of ipecacuan and opium, Ed. Pulvis ipecacuanhæ compositus, Lond. (Dover's powder.)
Take of ipecacuan powder and opium, of each equal parts; sulphat of potass eight parts. Rub them together into a fine powder.

Dose from 15 grains to half a drachm.

Pulvis opiatus, opiate powder.
Take of opium one part; prepared carbonat of lime nine parts. Rub them together to a fine powder.

Pulvis opiatus, opiate powder, Ph. Lond.
Take of hard purified opium, rubbed to powder, one drachm; prepared burnt hartshorn nine drachms. Mix them.

Pulvis scammonii compositus, compound powder of scammony.
Take of scammony, supertartrite of potass of each equal parts. Rub them together into a very fine powder.

Dose from 10 grains to a scruple.

Pulvis scammonii compositus, compound powder of scammony, Ph. Lond.
Take of scammony, extract of jalap, of each two ounces; ginger half an ounce. Rub them to powder separately, and mix them.

Dose about ten grains.

Pulvis scammonii compositus cum aloe, compound powder of scammony with aloes, Ph. Lond.
Take of scammony six drachms; extract of jalap, socotorine aloes, of each one ounce and a half; ginger half an ounce. Rub them to powder separately, and mix them.

Dose 10 or 15 grains.

Pulvis scammonii cum calomelane, powder of scammony with calomel, Ph. Lond.
Take of scammony half an ounce; calomel and refined sugar, of each two drachms. Rub them separately to powder, and mix them.

Dose from 10 grains to 15.

Pulvis sulphatis aluminæ compositus, compound powder of sulphat of argil.
Take of sulphat of argil four parts; kino one part. Rub them into a fine powder.

A styptic powder principally used externally.

Pulvis aloes cum canella, powder of aloes with canella, Ph. Lond.
Take of socotorine aloes one pound; white canella three ounces. Rub them separately to powder, and mix them.

This is generally given in spirits as a tincture.

Pulvis aloes cum guaiaco, powder of aloes with guaiac, Ph. Lond.
Take of socotorine aloes one ounce and a half; guaiac gum-resin one ounce; aromatic powder half an ounce. Rub the aloes and guaiac into powder separately, then mix them with the aromatic powder.

This is seldom used: dose 15 or 20 grains.

Pulvis aloes cum ferro, powder of aloes with iron, Ph. Lond.
Take of socotorine aloes an ounce and a half; myrrh two ounces; dried extract of gentian and sulphat of iron, of each an ounce. Rub them separately to powder, and mix them.

Dose from 10 to 15 grains.

Pulvis cerussæ compositus, compound powder of ceruss, Ph. Lond.
Take of cerusse five ounces; sarcocolla one ounce and a half; tragacanth half an ounce. Rub them together into powders.

This is used diffused in water as an injection and collyrium.

Pulvis contrayervæ compositus, compound powder of contrayerva, Ph. Lond.
Take of contrayerva rubbed to powder, five ounces; compound powder of crab's claws one pound a half.

This is a useless combination.

Pulvis myrrhæ compositus, compound powder of myrrh, Ph. Lond.
Take of myrrh, dried savin, dried rue, Russian castor, of each an ounce. Rub them together to a powder.

Dose a scruple, or half a drachm.

Pulvis sennæ compositus, compound powder of senna, Ph. Lond.
Take of senna, crystals of tartar, of each two ounces; scammony half an ounce; ginger two drachms. Rub the scammony separately, the others together, into a powder, and mix them.

Dose from half a drachm to a drachm.

Pulvis tragacanthæ compositus, compound powder of tragacanth, Ph. Lond.
Take of tragacanth powdered, gum arabic, starch, of each one ounce and a half; refined sugar, three ounces. Rub them into a powder together.

Dose one or two drachms.

Electuaria, electuaries.

Electuarium aromaticum, aromatic electuary, Ed. Confectio aromatica, Lond.
Take of aromatic powder one part; syrup of orange-peel two parts. Mix beating them well together so as to form an electuary.

Electuarium cassiæ fistulæ, electuary of purging cassia, Ed. El. cassiæ, Lond.
Take of cassia pulp in pods four parts; tamarind pulp, and manna, of each one part; syrup of pale rose four parts. Dissolve the manna beat in a mortar, in the syrup, with a gentle heat; then add the pulps, and by continuing the heat, reduce the mixture to a proper consistence.

This is scarcely used.

Electuarium cassiæ sennæ, electuary of senna, Ed. Elect. sennæ, Lond.
Take of senna leaves eight ounces; seeds of coriander four ounces; liquorice root three ounces; figs one pound; pulp of tamarind, of cassia, and of prunes, of each half a pound; sugar two pounds and a half. Rub the senna with the coriander seeds; and separate by passing through a sieve, ten ounces of mixed powders. Let the residuum with the figs and liquorice be boiled in four pounds of water down to one-half, then express and strain. Evaporate the strained liquor to about one pound and a half: afterwards add the sugar so as to form a syrup; add the syrup gradually to the pulps, and lastly mix in the powder.

This is the well known lenitive electuary. Dose from half an ounce to an ounce.

Electuarium catechu, electuary of catechu.
Take of catechu extract four ounces; kino three ounces; cinnamon and nutmeg of each one ounce; opium, diffused through a sufficient quantity of Spanish white wine, one drachm and a half; syrup of red rose boiled to the consistence of honey, two pounds and a quarter. Reduce to powder the solid ingredients, and mixing them with the opium and syrup, form an electuary.

In this electuary, formerly called japonic confection, one grain of opium is contained in rather more than three drachms of the mass.

Electuarium opiatum, opiate electuary, Ed. Confectio opiata, Lond.
Take of aromatic powder six ounces; Virginian snake root finely powdered, three ounces; opium, diffused in a sufficient quantity of white wine, half an ounce; syrup of ginger, one pound. Mix so as to make an electuary.

This preparation has been inserted in the Pharmacopœia, in the place of the complicated mithridate of the antients, and theriaca Andromachi.

Electuarium scammonii, electuary of scammony, Ph. Lond.
Take of scammony powdered one ounce and a half; cloves and ginger, of each six drachms; oil of caraway half a drachm; syrup of roses as much as may be sufficient. Mix the aromatics rubbed together into a powder, with the syrup; then add the scammony, and lastly the oil of caraway.

A stimulant purgative; dose 1 drachm or more.

Pilulæ, pills.

Pilulæ aloeticæ, aloetic pills.
Take of socotorine aloes in powder, soap, of each equal parts. Beat them with common syrup, so as to form a mass fit to be made into pills.

Pilulæ aloes composita, compound aloes pills, Ph. Lond.
Take of socotorine aloes in powder one ounce; extract of gentian half an ounce; oil of caraway two scruples; syrup of ginger as much as necessary. Beat them together.

Dose 2 pills, or 10 grains.

Pilulæ aloes cum assafœtida, pills of aloes with assafœtida.
Take of socotorine aloes, assafœtida, soap, of each equal parts. Beat them with mucilage of gum arabic into a mass.

Dose 2 or 3 pills.

Pilulæ aloes cum colocynthide, pills of aloes with colocynth.
Take of socotorine aloes, scammony, of each eight parts; colocynth four parts; sulphat of potass with sulphur, oil of cloves, of each one part. Let the aloes and scammony with the salt be reduced to powder; then let the colocynth be rubbed into a fine powder, and the oil be added. Lastly,

beat them into a mass with the mucilage of gum arabic.

Dose 2 pills. It is a powerful cathartic.

Pilulæ aloes cum myrrha, pills of aloes with myrrh, Ed. and Lond.

Take of socotorine aloes four parts; myrrh two parts; saffron one part. Beat them with simple syrup into a mass.

This is in frequent use as a purgative. Dose 2 or 3 pills.

Pilulæ assafœtidæ compositæ, compound assafœtida pills.

Take of assafœtida, galbanum, myrrh, of each eight parts; rectified oil of amber one part. Beat them with simple syrup into a mass.

Dose 2 or 3 pills.

Pilulæ galbani compositæ, compound pills of galbanum, Lond.

Take of galbanum, opoponax, myrrh, sagapenum, of each one ounce; assafœtida half an ounce; syrup of saffron as much as may be sufficient. Beat them together.

These pills are nearly similar to the preceding.

Pilulæ ammoniareti cupri, pills of ammoniaret of copper.

Take of ammoniaret of copper sixteen grains; crumb of bread four scruples; water of carbonat of ammonia, as much as is sufficient. Beat them into a mass which is to be divided into thirty pills.

Dose 1 pill.

Pilulæ hydrargyri, mercurial pills, Ed. and Lond.

Take of purified quicksilver, conserve of the red rose, of each one ounce; starch two ounces. Rub the quicksilver with the conserve in a glass mortar, until the globules disappear, adding, as occasion shall require, a little gum arabic mucilage; then add the starch, and beat with a little water into a mass, which immediately divide into 480 pills.

Dose 2 pills, gradually increased.

Pilulæ opiatæ, opiate pills, Ed. Pilulæ opii, Lond.

Take of opium one part; extract of liquorice seven parts; Jamaica pepper two parts. Mix separately the opium and the extract, softened with diluted alcohol, and beat them into a pulp; then add the pepper previously reduced to powder, and beat them into a mass.

In the Ph. L. the pepper is omitted.

Pilulæ rhæi compositæ, compound rhubarb pills.

Take of rhubarb root one ounce; socotorine aloes six drachms; myrrh half an ounce; oil of peppermint half a drachm. Beat them with syrup of orange-peel into a mass.

Dose 2 pills.

Pilulæ scilliticæ, squill pills, Ed. Pilulæ scillæ, Lond.

Take of dried squills powdered one scruple; gum ammoniac, smaller cardamom seeds in powder, and extract of liquorice, of each one drachm. Beat them into a mass with simple syrup.

Dose 2 pills.

Trochisci, troches, or lozenges.

Trochisci carbonatis calcis, troches of carbonat of lime, Ed. Trochisci cretæ, Lond.

Take of prepared carbonat of lime four ounces; gum arabic one ounce; nutmeg one drachm; refined sugar six ounces. Rub these into powder, and with water form it into a mass fit for making troches.

Trochisci glycyrrhizæ, liquorice troches, Ed. and Lond.

Take of extract of liquorice and gum arabic, of each one part; refined sugar two parts. Let these be dissolved in warm water and strained; then with a gentle heat evaporate the solution into a mass, which is to be divided into troches.

Trochisci glycyrrhizæ cum opio, liquorice troches with opium.

Take of opium two drachms; tincture of tolu balsam half an ounce; simple syrup eight ounces; extract of liquorice softened with warm water, and gum arabic in powder, of each five ounces. First rub the opium with the tincture; then gradually add the syrup and the extract; afterwards sprinkle in by degrees the gum arabic powder, and lastly dry the mass, that it may be made into troches, each weighing ten grains.

These are useful in relieving catarrhal cough.

Trochisci gummosi, gum troches.

Take of gum arabic four parts; starch one part; refined sugar twelve parts. These, powdered, are to be formed with rose water into a mass, fit for making troches.

Trochisci nitratis potassæ, troches of nitrat of potass, Ed. Trochisci nitri, Lond.

Take of nitrat of potass one part; refined sugar three parts. Beat them to powder, and make them, with gum tragacanth mucilage, into a mass, proper for forming troches.

Trochisci amyli, starch troches, Lond.

Take of starch one ounce and a half; liquorice six drachms; Florentine orris half an ounce; refined sugar one pound and a half. Rub these to powder, and with tragacanth mucilage form troches. They may be made, if preferred, without the orris.

Trochisci magnesiæ, magnesia troches, Lond.

Take of burnt magnesia four ounces; refined sugar two ounces; powdered ginger one scruple. Rub them together, and adding mucilage of gum arabic, form them into troches.

Trochisci sulphuris, sulphur troches, Ph. Lond.

Take of washed flowers of sulphur two ounces; refined sugar four ounces: mucilage of quince seeds as much as sufficient. Rub them together and form troches.

Linimenta, unguenta, et cerata, liniments, ointments, and cerates.

In making these compositions, fatty and resinous substances are to be melted with a gentle heat, constantly stirring, and sprinkling in the dry ingredients, if there are any, in fine powder, until by cooling the mixture acquires a stiffness of consistence.

Linimentum simplex, simple liniment.

Take of olive oil four parts; white wax one part.

Unguentum simplex, simple ointment.

Take of olive oil five parts; white wax two parts.

Ceratum simplex, simple cerate, Ed. Ceratum spermatis ceti, Lond.

Take of olive oil six parts; white wax three parts; spermaceti one part.

The above three compositions only differ in consistence.

Unguentum adipis suillæ, ointment of hog's lard, Ph. Lond.

Take of prepared hog's lard two pounds; rose water three ounces. Beat the lard with the rose water until they are mixed, then liquefy with a gentle heat, and put it aside that the water may subside. After pour off the ointment, stirring it constantly until it has cooled.

Unguentum resinosum, resinous ointment, Ed. Ung. resinæ flavæ, Lond.

Take of hog's lard eight parts; white resin five parts; yellow wax two parts.

This ointment is used principally when suppuration is wished to be promoted.

Unguentum pulveris meloes vesicatorii, ointment of the powder of cantharides, Ed. Ceratum cantharidis, Lond.

Take of resinous ointment seven parts; powder of cantharides, one part.

The cantharides ointment is used principally when the discharge, excited by a blister, is wished to be preserved and converted into a purulent matter.

Unguentum infusi meloes vesicatorii, ointment of infusion of cantharides, Ed. Ung. cantharidis, Lond.

Take of cantharides, white resin, yellow wax, of each one part; Venice turpentine and hog's lard, of each two parts; boiling water four parts. Macerate the cantharides in the water for a night, and strain the liquor, pressing it strongly: having added the lard boil the liquor until the water is evaporated, then add the wax and resin. These being melted and removed from the fire, add the turpentine.

This is milder than the preceding.

Unguentum subacetitis cupri, ointment of subacetite of copper (verdigris).

Take of resinous ointment fifteen parts; subacetite of copper one part.

An escharotic applied principally to foul and obstinate ulcers.

Unguentum hydrargyri, ointment of quicksilver (blue ointment).

Take of quicksilver, mutton suet, of each one part; hog's lard three parts. Carefully rub them in a mortar until the quicksilver globules disappear. It may be made with double or triple the quantity of quicksilver.

Unguentum hydrargyri fortius, stronger ointment of quicksilver, Ph. Lond.

Take of purified quicksilver two pounds; prepared hog's lard twenty-three ounces; prepared tallow one ounce. Rub first the quicksilver with the tallow, and a little lard, until the globules disappear. Then add the remaining lard so as to form an ointment.

Unguentum hydrargyri mitius, milder ointment of quicksilver, Ph. Lond.

Take of the stronger ointment of quicksilver one part; prepared hog's lard two parts. Mix them. One drachm of the stronger ointment to be introduced by friction; the weaker ointments are superfluous.

Unguentum oxidi hydrargyri cinerei, ointment of grey oxide of quicksilver.

Take of grey oxide of quicksilver one part; hog's lard three parts.

This it has been supposed will prove more active than the common blue ointment, on account of the quicksilver being more oxidised.

Unguentum oxidi hydrargyri rubri, ointment of red oxide of quicksilver.

Take of red oxide of quicksilver by nitric acid one part; hog's lard eight parts.

This is chiefly used to remove fungi from ulcers.

Unguentum calcis hydrargyri albi, ointment of white calx of quicksilver, Ph. Lond.

Take of white calx of quicksilver one drachm; ointment of hog's lard one ounce and a half. Mix them so as to form an ointment.

Used principally in psora.

Unguentum nitratis hydrargyri fortius, stronger ointment of nitrat of quicksilver, Ed. Ung. hydrargyri nitrati, Lond.

Take of purified quicksilver one part; nitrous acid two parts; hog's lard twelve parts. Digest the quicksilver with the nitrous acid in a sand-bath, until a solution is obtained, which while hot is to be mixed with the hog's lard melted, and beginning to cool. Beat the mixture thoroughly in a glass mortar, so as to make an ointment.

Unguentum nitratis hydrargyri mitius, milder ointment of nitrat of quicksilver.

This is made in the same manner as the last with a triple proportion of lard.

Unguentum acidi nitrosi, ointment of nitrous acid.

Take of hog's lard one pound; nitrous acid six drachms. Mix gradually the acid with the melted lard, and during the cooling of the mixture, beat it thoroughly.

Unguentum oxidi plumbi albi, ointment of white oxide of lead.

Take of simple ointment five parts; white oxide of lead one part.

Unguentum acetitis plumbi, ointment of acetite of lead, Ed. Ung. cerussæ acetatæ, Lond.

Take of simple ointment twenty parts; acetite of lead one part.

Ceratum lithargyri acetati compositum, compound cerate of acetated litharge, Ph. Lond.

Take of water of acetated litharge two ounces and a half; yellow wax four ounces; olive oil nine ounces; camphor half a drachm. Rub the camphor with a little of the oil. Melt the wax with the remaining oil, and as soon as the mixture begins to thicken, pour on gradually the water of acetated litharge, and stir constantly until the mixture has cooled; then mix with it the camphor rubbed with oil.

This is the common Goulard's cerate.

Ceratum carbonatis zinci impuri, cerate of impure carbonat of zinc, Ed. Cerat. lapidis calaminaris, Lond.

Take of simple cerate five parts; prepared impure carbonat of zinc one part.

This is the common healing cerate.

Unguentum oxidi zinci impuri, ointment of impure oxide of zinc, Ed. Ung. tutiæ, Lond.

Take of simple liniment five parts; prepared impure oxide of zinc one part.

Principally employed in chronic inflammation of the eyes.

Unguentum oxidi zinci, ointment of oxide of zinc.

Take of simple liniment six parts; oxide of zinc one part.

This is employed likewise in ophthalmia.

Unguentum picis, ointment of tar, Ed. and Lond.

Take of tar five parts; yellow wax two parts.

The chief use of tar ointment is in tinea capitis.

Unguentum sulphuris, ointment of sulphur, Ed. and Lond.

Take of hog's lard four parts; sublimed sulphur one part. To each pound of this ointment add essential oil of lemon, or oil of lavender, half a drachm.

This is deemed one of the most efficacious ointments in psora.

Unguentum elemi compositum, compound ointment of elemi, Ph. Lond.

Take of elemi one pound; common turpentine ten ounces; prepared suet two pounds; olive oil two ounces. Melt the elemi with the suet, and having removed it from the fire, mix it immediately with the turpentine and oil, then strain the mixture.

Unguentum hellebori albi, ointment of white hellebore, Ph. Lond.

Take of white hellebore rubbed to powder one ounce; ointment of hog's lard four ounces; essence of lemon half a scruple. Mix them so as to form an ointment.

This ointment is often employed in psora.

Unguentum sambuci, ointment of elder, Ph. Lond.

Take of elder flowers four pounds; prepared mutton suet three pounds; olive oil one pound. Beat the elder flowers with the suet and oil, until they become friable; then pour out the fluid and strain it.

Ceratum saponis, cerate of soap, Ph. Lond.

Take of soap eight ounces; yellow wax ten ounces; litharge in powder one pound; olive oil one pound; vinegar one gallon. Boil the vinegar with the litharge on a gentle fire, constantly stirring, until the mixture becomes uniform and thick; then mix with it the other ingredients, so as to form a cerate.

Emplastra, plasters.

Emplastrum simplex, simple plaster, Ed. Emp. ceræ comp. Lond.

Take of yellow wax three parts; mutton suet and resin of each two parts.

This is principally employed as an application after a blister.

Emplastrum oxidi plumbi semivitrei, plaster of semivitreous oxide of lead, Ed. Emp. lithargyri, Lond.

Take of the semivitreous oxide of lead one part; olive oil two parts. Having added water, boil them, stirring constantly, until the oil and oxide unite and form plaster.

This is chiefly applied to excoriations or trivial wounds.

Emplastrum resinosum, resinous plaster, Ed. Emp. lithargyri cum resina, Lond.

Take of plaster of semivitreous oxide of lead five parts; resin one part.

This is the common adhesive plaster.

Emplastrum oxidi ferri rubri.

Take of plaster of semivitreous oxide of lead twenty-four parts; resin six parts; yellow wax, olive oil, of each three parts; red oxide of iron eight parts. Rub the red oxide of iron with the oil, and add to it the other ingredients melted.

The strengthening plaster, applied principally in lumbago.

Emplastrum assafœtidæ, assafœtida plaster.

Take of plaster of semivitreous oxide of lead, assafœtida, galbanum, yellow wax, of each equal parts.

This is sometimes used in hysteric complaints, applied to the breast.

Emplastrum gummosum, gum plaster.

Take of plaster of semivitreous oxide of lead eight parts; ammoniac, galbanum, yellow wax, of each one part.

A stimulant plaster employed to encourage suppuration.

Emplastrum hydrargyri, quicksilver plaster, Ed. Emp. lithargyri cum hydrargyro, Lond.

Take of olive oil, resin, of each one part; quicksilver three parts; plaster of semivitreous oxide of lead six parts. Rub the quicksilver with the oil and resin melted together, and then cooled, until the globules disappear; then add gradually the plaster of semivitreous oxide of lead, melted, and mix them all together.

A discutient plaster.

Emplastrum saponaceum, soap plaster, Ed. Emp. saponis, Lond.

Take of plaster of semivitreous oxide of lead four parts; gum plaster two parts; sliced soap one part. Mix the soap with the plasters melted together.

This as a discutient is inferior to the preceding.

Emplastrum meloes vesicatorii, plaster of cantharides, Ed. Emp. cantharidis, Lond.

Take of mutton suet, yellow wax, resin and cantharides, of each equal weights. The Spanish flies rubbed with fine powder, are to be used with other ingredients, melted together, and removed from the fire.

Common blistering plaster.

Emplastrum meloes vesicatorii compositum, compound plaster of cantharides.

Take of Burgundy pitch eighteen parts; turpentine and cantharides of each twelve parts; subacetite of copper two parts; mustard seed and black pepper of each one part. To the melted Burgundy pitch and wax, add the turpentine. When the liquefaction is complete, and while the fluid is still warm, sprinkle in the other ingredients, powdered and mixed, stirring constantly so as to form plaster.

Emplastrum ammoniaci cum hydrargyro, plaster of ammoniac with quicksilver, Ph. Lond.

Take of strained ammoniac one pound; purified quicksilver three ounces; sulphureted oil one drachm, or as much as sufficient. Rub the quicksilver with the sulphureted oil, until the globules disappear; then gradually add the melted ammoniac and mix them.

Emplastrum cumini, cumin plaster, Ph. Lond.

Take of cumin, caraway, bay berries, of each three ounces; Burgundy pitch three pounds; yellow wax three ounces. With the pitch and wax melted, mix the other ingredients rubbed to powder.

Emplastrum ladani compositum, compound plaster of ladanum, Ph. Lond.

Take of ladanum three ounces; frankincense

10

one ounce; cinnamon in powder, expressed oil of nutmeg, of each half an ounce; oil of spearmint one drachm. To the melted frankincense add first the ladanum, softened by heat, then the expressed oil of nutmeg; afterwards mix these and the cinnamon with the oil of mint, and beat them in a warm mortar. Keep the plaster in a close vessel.

This as a stimulant application is superior to the preceding.

Emplastrum lithargyri compositum, compound litharge plaster, Ph. Lond.

Take of litharge plaster three pounds; strained galbanum, eight ounces; common turpentine, ten drachms; frankincense, three ounces. Mix the frankincense, rubbed to powder, with the galbanum and turpentine melted, and add the litharge plaster melted with a slow fire.

Emplastrum picis Burgundicæ compositum, compound Burgundy pitch plaster, Ph. Lond.

Take of Burgundy pitch two pounds; ladanum, one pound; yellow resin, yellow wax, of each four ounces; expressed oil of nutmeg, one ounce. To the pitch resin and wax melted together, add first the ladanum, then the oil of nutmeg.

Emplastrum thuris compositum, compound frankincense plaster, Ph. Lond.

Take of frankincense half a pound; dragon's blood, three ounces; litharge plaster, two pounds. To the litharge plaster melted, add the others rubbed to powder.

This is employed as a strengthening plaster.

Cataplasmata, cataplasms.

Cataplasma aluminis, alum cataplasm, Ph. Lond.

Take the whites of two eggs, agitate them with a piece of alum until a coagulum is formed.

Applied in some kinds of ophthalmia.

Cataplasma cumini, cumin cataplasm, Ph. Lond.

Take of cumin one pound; bay berries, dried scordium, Virginian snake root, of each three ounces; cloves one ounce. Rub them all together into powder, and having added three times their weight of honey, form a cataplasm.

Cataplasma sinapeos, mustard cataplasm, Ph. Lond.

Take of mustard in powder, crumbs of bread, of each half a pound; warm vinegar as much as is sufficient. Mix so as to form a cataplasm.

This is the sinapism which is usually applied to the soles of the feet, as a stimulant in the last stages of typhoid fever, and in other affections of debility.

A table shewing the quantity of opium, antimony, and quicksilver, in the different compound medicines of the Edinburgh and London Pharmacopœias.

Vinum tartritis antimonii, Ed. has two grains of tartrite of antimony in each ounce. Vinum antimonii tartarisati, Lond. has four grains of the tartrite of antimony (antim. tart.) in each ounce.

Tinctura opii, Ed. has three grains and a half of opium to one drachm of the tincture. Tinct. opii, Lond. has one grain of opium in each thirteen drops of the tincture.

Tinct. opii ammoniata, Ed. has rather more than a grain of opium in each drachm of the tincture. Tinct. opii camphorata, Lond. has a grain of opium to half an ounce of the tincture.

Tinctura saponis cum opio, Ed. has a scruple of opium in each ounce of the liquid.

Pulvis ipecacuanhæ et opii, Ed. has a grain of opium in ten grains of the powder. Pulv. ipecacuanhæ compositus, Lond. the same.

Pulvis opiatus, Ed. and Lond. ten grains contain a grain of opium.

Electuarium catechu, Ed. has in each ounce about two grains and a half of opium.

Electuarium opiatum, Ed. has in each drachm a grain and a half of opium. Confectio opiata, Lond. has one grain of opium to thirty-six of the mass.

Pilulæ hydrargyri, Ed. has fifteen grains of mercury to each drachm, Lond. a grain to each two grains and a half.

Pilulæ opiatæ, Ed. Ten grains of the mass contain a grain of opium, Lond. five grains contain a grain.

Trochisci glycirrhizæ cum opio, Ed. One drachm of the mass has a grain of opium.

Unguentum nitratis hydrargyri fortius et mitius, Ed. The first has in each drachm four grains of quicksilver and eight of nitrous acid; the second has half a grain of quicksilver and one of nitrous acid, in each scruple.

Unguentum hydrargyri, Ed. in each drachm has twelve grains of quicksilver. Ung. hyd. fortius, Lond. has a drachm of quicksilver in two of the mass; the mitius has a drachm in five drachms.

Emplastrum hydrargyri, Ed. has in each drachm about sixteen grains of quicksilver.

Table of the gradations in doses of medicine, from Mr. Murray's Materia Medica.

Suppose that the proper dose of the medicine to be given is one drachm:

For a person from 14 to 21 years, it will be two-thirds or two scruples.

For a person from 7 to 14 years, it will be one-half or half a drachm.

For a person from 4 to 7 years, it will be one-third or a scruple.

For a person of 4 years, it will be one-fourth or fifteen grains.

For a person of 3 years, it will be one-sixth or half a scruple.

For a person of 2 years, it will be one-eighth, or eight grains.

For a person of 1 year, it will be one-twelfth or five grains.

PHARNACEUM, a genus of the pentandria trigynia class of plants, without any corolla; but the calyx resembles one, being coloured on the inside, and its edges thin; the fruit is an oval capsule, obscurely trigonal, and in part covered by the cup; it consists of three cells, in which are contained numerous nitid, orbiculated, and depressed seeds, surrounded with a margin.

PHARO is the name of a game of chance, the principal rules of which are: the banker holds a pack consisting of 52 cards; he draws all the cards one after the other, and lays them down alternately at his right and left hand; then the ponte may at his pleasure set one or more stakes upon one or more cards, either before the banker has begun to draw the cards, or after he has drawn any number of couples. The banker wins the stake of the ponte when the card of the ponte comes out in an odd place on his right hand, but loses as much to the ponte when it comes out in an even place on his left hand. The banker wins half the ponte's stake when it happens to be twice in one couple. When the card of the ponte, being but once in the stock, happens to be the last, the ponte neither wins nor loses; and the card of the ponte being but twice in the stock, and the last couple containing his card twice, he then loses his whole stake. De Moivre has shewn how to find the gain of the banker in any circumstance of cards remaining in the stock, and of the number of times that the ponte's card is contained in it. Of this problem he enumerates four cases, viz. when the ponte's card is once, twice, three, or four times in the stock. In the first case, the gain of the banker is $\frac{1}{n}$, n being the number of cards in the stock. In the second case, his gain is $\frac{\overline{n-2}\times y}{n\times\overline{n-1}}+\frac{2}{n\times\overline{n-1}}$, or $\frac{\frac{1}{2}n-1}{n\times\overline{n-1}}$, supposing $y=\frac{1}{2}$. In the third case, his gain is $\frac{3y}{2\times\overline{n-1}}$, or $\frac{3}{n\times\overline{n-1}}$, supposing $y=\frac{1}{2}$. In the fourth case, the gain of the banker, or the loss of the ponte, is $\frac{2n-5}{\overline{n-1}\times\overline{n-3}}y$, or $\frac{2n-5}{2\times\overline{n-1}\times\overline{n-3}}$, supposing $y=\frac{1}{2}$. De Moivre has calculated a table, exhibiting this gain or loss for any particular circumstance of the play; and he observes, that at this play the least disadvantage of the ponte, under the same circumstance of cards remaining in the stock, is when the card of the ponte is but twice in it; the next greater when three times, the next when once, and the greatest when four times. He has also demonstrated, that the whole gain per cent. of the banker upon all the money that is adventured at this game, is 2*l.* 19*s.* 10*d.* See De Moivre's Doctrine of Chances, p. 77.

PHARUS, a genus of the hexandria order, in the monœcia class of plants, and in the natural method ranking under the fourth order, gramina. The male calyx is a bivalved uniflorous glume; the corolla, a bivalved glume; the female calyx the same with the male; the corolla an uniflorous, long, and wrapping glume. There is but one seed. There are three species, grasses of the East and West Indies.

PHARYNX. See ANATOMY.

PHASCUM, in botany, a genus of the order of musci, belonging to the cryptogamia class of plants. The anthera is operculated, with a ciliated mouth; the calyptræ are minute.

PHASEOLUS, *kidney-bean*, a genus of the diadelphia decandria class of plants, the corolla whereof is papilionaceous; the vexillum is cordated, obtuse, emarginated, and reclined with reflex sides; the alæ are roundish, of the same length with the vexillum, and stand upon long ungues; the carina is narrow, and revolves spirally in a contrary direction to the sun; the fruit is a long, straight, coriaceous, and obtuse pod; the seeds are oblong, compressed, and kidney-shaped. There are 21 species.

PHASES. See ASTRONOMY.

PHASIANUS, in ornithology, a genus belonging to the order of gallinæ. The cheeks are covered with a smooth naked skin. Phasianus is derived from the river Phasis, the banks of which are the native habitation of the pheasant. The species are:

1. The gallus, or common cock and hen, with a compressed caruncle, or fleshy comb on the top of the head, and two caruncles or wattles under the chin. The ears are naked, and the tail is compressed and erected. Of all birds, perhaps this species affords the greatest number of varieties, there being scarcely two to be found that exactly resemble each other in plumage and form. The tail, which makes such a beautiful figure in the generality of these birds, is yet found entirely wanting in others; and not only the tail, but the rump also. The toes, which are usually four in all animals of the poultry kind, yet in a variety of the cock are found to amount to five. The feathers, which lie so sleek and in such beautiful order in most of those we are acquainted with, are in a peculiar breed all inverted, and stand staring the wrong way. Nay, there is a species that comes from Japan, which, instead of feathers, seems to be covered over with hair.

It is not well ascertained when the cock was first made domestic in Europe; but it is generally agreed that we first had him in our western world from the kingdom of Persia.

In his wild condition, his plumage is black and yellow, and his comb and wattles yellow and purple. There is another peculiarity also in those of the Indian woods; their bones, which, when boiled, with us are white, as every body knows, in those are as black as ebony.

No animal in the world has greater courage than the game cock, when opposed to one of his own species; and in every part of the world where refinement and polished manners have not entirely taken place, cock-fighting is a principal diversion. In China, India, the Philippine islands, and all over the East, cock-fighting is the sport and amusement even of kings and princes. With us it is declining every day; and it is hoped it will in time be utterly banished.

The cock claps his wings before he sings or crows. His sight is very piercing; and he never fails to cry in a peculiar manner when he discovers any bird of prey in the air. His extraordinary courage is thought to proceed from his being the most salacious of all other birds whatsoever. A single cock suffices for ten or a dozen hens.

The hen seldom clutches a brood of chickens above once a season, though instances have been known in which they have produced two. The number of eggs a domestic hen will lay in the year are above two hundred, provided she is well fed and supplied with water and liberty. Ten or twelve chickens are the greatest number that a good hen can rear and clutch at a time; but as this bears no proportion to the number of her eggs, schemes have been imagined to clutch all the eggs of a hen, and thus turn her produce to the greatest advantage. See Hatching.

Of this species Mr. Latham enumerates no less than 13 permanent varieties, beginning with the wild cock, which is a third less in the body than the domestic cock. This variety he imagines to be the original stock whence all our domestic varieties have sprung. They appear to be natives of the forests of India. There are but few places, however, as Mr. Latham goes on to observe, where the different voyagers have not met with cocks and hens, either wild or tame; and mention has been particularly made of finding them at St. Jago, Pulo Condore, isle of Timor, Philippine and Molucca Isles, Sumatra and Java, New Guinea, Tinian, and most of the isles of the South Seas.

2. The motmot, or Guinea pheasant, is brownish, somewhat red below, with a wedge-like tail, and wants spurs. 3. The colchicus is red, with a blue head, a wedge-shaped tail, papilous cheeks. It is a native of Africa and Asia. 4. The argus is yellowish, with black spots, a red face, and a blue crest on the back part of the head. It is found in Chinese Tartary. 5. The pictus has a yellowish crest, a red breast, and a wedge-shaped tail. It is a native of China. See Plate Nat. Hist. fig. 331.

Mr. Latham enumerates nine different species of pheasants, and of the common pheasant he reckons six varieties. The first which he describes is the superb pheasant. This bird Linnæus described from the various representations of it painted on paper-hangings and China-ware; and farther confirmed by a figure and description in a Chinese book which came under his inspection.

"We have lately seen," says Latham, "a drawing of the tail feather of a bird of the pheasant kind, which measured above six feet in length, and which, it is probable, must have belonged to some bird not hitherto come to our knowledge. The drawing is in the possession of major Davies, who took it from the original feather; two of which were in the possession of a gentleman of his acquaintance, and were brought from China. They are exactly in shape of the two middle feathers of the painted pheasant; the general colour is that of a fine blue grey, margined on the sides with a rufous cream-colour, and marked on each side the shaft with numerous bars of black; between 70 and 80 bars in all, those on the opposite sides of the shaft seldom corresponding with each other.

"The argus, though a native of China, is very commonly found in the woods of Sumatra, where it is called coo-ow. It is found extremely difficult to be kept alive for any considerable time after catching it in the woods; never for more than a month. It seems to have an antipathy to the light, being quite inanimate in the open day; but when kept in a dark place it appears perfectly at ease, and sometimes makes its note or call, from which it takes its name, and which is rather plaintive, and not harsh like that of a peacock. The flesh resembles that of the common pheasant."

For the parraka, which Mr. Latham reckons a variety of the common pheasant, and which is found in the woods of America, and remarkable for its loud cry, see Plate Nat. Hist. fig. 330.

PHASMA, a genus of insects of the order hemiptera; the generic character is, head large; antennæ filiform; eyes small, rounded; stemmata three, between the eyes; wings four, membranaceous, the upper pair abbreviated, the lower pleated; feet formed for walking.

This, which is not, strictly speaking, a Linnæan genus, being formed from some of the Linnæan mantes, differs from the genus mantis in having all the legs equally formed for walking, or without the falciform joint, which distinguishes the fore-legs in the genus mantis. The antennæ are setaceous, and the head large and broad: to these characters may be added the shortness of the upper wings or hemelytra, which scarcely cover more than about a third part of the body, while the lower wings are often very large and long. In their mode of life the phasmata differ from the mantes; feeding entirely on vegetable food. In the extraordinary appearance of many of its species this genus is at least equal to that to which we allude.

The most remarkable is the phasma gigas, or giant phasma. (Mantis gigas, Lin.) This insect measures six or eight inches in length, and is of a very lengthened shape both in thorax and abdomen, which are of a subcylindric form, the thorax being roughened on the edges and upper surface by numerous small spines or tubercles; the upper wings are small, green, and veined like the leaves of a plant, while the lower are very ample, reaching half the length of the body or farther, of a very pale transparent brown, elegantly varied and tesselated by darker spots and patches: the legs are of moderate length, with the joints roughened by spines. The larva and pupa of this species bear a more singular appearance than even the complete insect, greatly resembling, on a general view, a piece of dry stick with several small broken twigs adhering to it; for this reason it has been generally known in collections by the name of the walking-stick, and under this title is figured in Edwards's Gleanings of Natural History, and many other publications. It is, however, probable, that though of a pale brown in its dry state, it is in reality green when living; the natural colour fading after death, as in many others of this tribe. It is a native of the island of Amboina. It may be added, that this insect either runs into several varieties as to size and some other particulars, or that there exist in reality many distinct species, which have been confounded under one common name.

The phasma dilatatum is another extraordinary species, and seems to have been first described in the fourth volume of the Transactions of the Linnæan Society, by Mr. John Parkinson.

It is supposed to be a native of Asia, and belongs to that tribe of insects which Stoll has called spectres, and which constitute a distinct genus from that of mantis. It measures six inches and a quarter from the upper part or top of the head to the extremity of the abdomen. The whole animal is of a flattened form, more especially on the abdomen, which measures about an inch and a half across in its broadest part: the thorax is of an obtusely rhomboidal form, the slides sloping each way from the flattish upper part. The whole thorax is not only edged with spines, but has also several very sharp ones distantly scattered over its surface. The head rises up backwards into an obtusely conic shape, and has several very strong and large spines or processes. The abdomen is edged, almost throughout its whole length, with a continued series of small spines, to the number of five on the side of each individual segment: the extreme segments are without spines. The thighs or first joints of the lower pair of legs are in this insect remarkably strong, of a somewhat triangular shape, and beset with some strong spines; but the tibiæ or second joints are armed with far larger and stronger ones. The general colour of the thorax, abdomen, and head, is brown in the dead, but might probably have been green in the living, animal. The wings are scarcely larger than the elytra or wing-sheaths, and seem originally to have been reddish; the tips are green. These wings are very strongly veined with brown fibres; the wing-cases are of a strong opake green, and were doubtless more vivid in the living insect: they have a great resemblance to a pair of leaves. The mouth has four palpi, which are rather long, and under the mouth are situated two leaf-shaped organs, perhaps belonging to the action of that part. The abdomen is terminated by a kind of boat-shaped organ, the keel of which possesses a considerable space beneath the abdomen, so that fewer segments appear on that part than above. The concavity of this organ is covered by a terminal scale and bifid process, constituting the tip of the abdomen on the upper part. On raising this valve, an ovum, nearly of the size of a pea, but of a more lengthened form, is discovered lying in the cavity beneath; and on inspecting farther into the cavity of the abdomen, a great many more ova, exactly similar, were found, to the number of five or six and twenty: these eggs are of a slightly oblong shape, but flattened at one end; they are of a brown colour, and marked all over with numerous impressed points, and have on one side a mark or double waved line, so disposed as to represent a kind of cross, as if carved on the surface; the flattened end is surrounded by a small rim or ledge, and seems to be the part which opens at the exclusion of the larva, since it readily separates from the rest. On immersing some of these ova in warm water, and opening them, the included yolk, of a deep yellow colour, and of the appearance of a transparent gum, was discovered; and this, when burned, afforded the usual smell of animal substances, but in some it was accompanied by a slight degree of fragrance.

Some insects of this genus, like the preceding, are remarkable for the extreme, and even deceptive resemblance which their upper wings bear to leaves of trees. This is a wise provision of nature for the security of the animal against the attacks of birds, as well as for the more ready attainment of its prey; since when sitting among the branches, it eludes the notice of both.

PHEASANT. See PHASIANUS.

PHELLANDRIUM, *water-hemlock*, a genus of the digynia order, in the pentandria class of plants. The florets of the disk are smaller; fruit ovate, even crowned, with the perianthium and pistillum. There are two species, one of which, viz. the aquaticum, is a native of Britain. This grows in ditches and ponds, but is not very common. The stalk is remarkably thick and dichotomous, and grows in the water. It is a poison to horses, bringing upon them, as Linnæus informs us, a kind of palsy, which, however, he supposes to be owing not so much to the noxious qualities of the plant itself, as to those of an insect which feeds upon it, breeding within the stalks, and which he calls curculio paraplecticus.

PHILADELPHUS, the *pipe-tree*, or *mock orange*, a genus of the monogynia order, in the icosandria class of plants. The species are:

1. The coronarius, white syringa, or mock orange, has been long cultivated in the gardens of this country as a flowering shrub; it is not well known in what country it is to be found native. 2. The scoparius. 3. The aromaticus. 4. The laniger. The propagation of all the sorts is very easy: they are increased by layers, cuttings, or suckers.

PHILLYREA, *mock privet*, a genus of the monogynia order, in the diandria class of plants. Each flower contains two males and one female. There are three species, all of them shrubby plants, and natives of France or Italy.

1. Phillyrea media, the oval-leaved phillyrea, or mock privet, or the medical-leaved phillyrea, a tall evergreen shrub, native of the south of Europe. 2. Phillyrea latifolia, the broad-leaved phillyrea, or mock privet, a tall evergreen shrub, native of the south of Europe. 3. Phillyrea angustifolia, the narrow-leaved phillyrea, or mock privet, a deciduous shrub, native of Spain and Italy.

PHILOLOGY, a science, or rather assemblage of several sciences, consisting of grammar, rhetoric, poetry, antiquities, history, and criticism.

PHILOSOPHY. See EXPERIMENTAL and NATURAL PHILOSOPHY, ETHICS, &c.

PHILYDRUM, a genus of the class and order monandria monogynia. The spathe is one-flowered; perianthium none; corolla four-petalled, irregular; capsule three-celled, many-seeded. There is one species, a herb of China.

PHLEBOTOMY. See SURGERY.

PHLEUM, *cat's-tail grass*, a genus of the triandria digynia class of plants, the corolla of which consists of two valves; and the seed, which is single, is included within the calyx and corolla. There are four species. See HUSBANDRY.

PHLOAS, a genus of vermes testacea; the animal an ascidia; shell bivalve, divaricate, with several lesser differently shaped accessory ones at the hinge; hinges recurved, united by a cartilage: in the inside, beneath the hinge, is an incurved tooth. The inhabitants of this genus perforate clay, spongy stones and wood, while in the younger state; and as they increase in size, enlarge their habitation within, and thus become imprisoned. They contain a phosphorous liquor of great brilliancy in the dark, and which illuminates whatever it touches or happens to fall upon. There are 12 species.

All that we can know with certainty is, that they must have penetrated these substances when very small, because the entrance of the hole in which the phloas lodges is always much less than the inner part of it, and indeed than the shell of the phloas itself. Hence some have supposed that they were hatched in holes accidentally formed in stones, and that they naturally grew of such a shape as was necessary to fill the cavity.

The holes in which these insects lodge, are usually twice as deep, at least, as the shells themselves are long; the figure of the holes is that of a truncated cone, excepting that they are terminated at the bottom by a rounded cavity, and their position is usually somewhat oblique to the horizon. The openings of these holes are what betray the phloas being in the stone; but they are always very small in proportion to the size of the fish. There seems to be no progressive motion of any animal in nature so slow as that of the phloas; it is immersed in the hole, and has no movement except a small one towards the centre of the earth; and this is only proportioned to the growth of the animal. Its work is very difficult in its motion; but it has great time to perform it in, as it only moves downwards, sinking itself deeper in the stone as it increases itself in bulk. That part by means of which it performs this is a fleshy substance placed near the lower extremity of the shell; it is of the shape of a lozenge, and is considerably large in proportion to the size of the animal; and though it is of a soft substance, it is not to be wondered at that in so long a time it is able, by constant work, to burrow into a hard stone. The manner of their performing this may be seen by taking one of them out of the stone, and placing it upon some soft clay; for they will immediately get to work in bending and extending that part allotted to dig for them, and in a few hours they will bury themselves in the mud in as large a hole as they had taken many years to make in the stone. They find little resistance in so soft a substance; and the necessity of their hiding themselves evidently makes them hasten their work. The animal is lodged in the lower half of the hole in the stone, and the upper half is filled up by a pipe of a fleshy substance and conical figure, truncated at the end. This they usually extend to the orifice of the hole, and place on a level with the surface of the stone; but they seldom extend it any farther than this. The pipe, though it appears single, is in reality composed of two pipes, or at least it is composed of two parts separated by a membrane. The use of this pipe or proboscis is the same with that of the proboscis of other shell-fish, to take in sea-water into their bodies, and afterwards to throw it out again. In the middle of their bodies they have a small green vessel, the use of which has not yet been discovered. This, when plunged in spirit of wine, becomes of a purple colour; but its colour on linen will not become purple in the sun like that of the murex; and even if it would, its quantity is too small to make it worth preserving.

The phloas is remarkable for its luminous quality. That this fish is luminous was noticed by Pliny, who observes that it shines in the mouth of the person who eats it; and if it touches his hands or clothes, it makes them luminous. He also says that the light depends upon its moisture. The light of this fish has furnished matter for various observations and experiments to M. Reaumur and the Bolognian academicians, especially Beccarius, who took so much pains with the subject of phosphoreal light.

M. Reaumur observes, that whereas other fishes give light when they tend to putrescence, this is more luminous in proportion to its being fresh; that when they are dried, their light will revive if they are moistened either with fresh or salt water, but that brandy immediately extinguishes it. He endeavoured to make this light permanent, but none of his schemes succeeded.

The attention of the Bolognian academicians was engaged to this subject by M. F. Marsilius, in 1724, who brought a number of these fishes, and the stones in which they were enclosed, to Bologna, on purpose for their examination.

Beccarius observed, that though this fish ceased to shine when it became putrid, yet that in its most putrid state it would shine, and make the water in which it was immersed luminous when it was agitated. Galeatius and Montius found that wine and vinegar extinguished this light; that in common oil it continued some days, but in rectified spirit of wine or urine, hardly a minute.

In order to observe in what manner this light was affected by different degrees of heat, they made use of a Reaumur's thermometer, and found that water rendered luminous by these fishes increased in light till the heat arrived to 45°, but that it then became suddenly extinct, and could not be revived again.

In the experiments of Beccarius, a solution of sea-salt increased the light of the luminous water; a solution of nitre did not increase it quite so much. Sal ammoniac diminished it a little, oil of tartar per deliquium nearly extinguished it, and the acids entirely. This water poured upon fresh calcined gypsum, rock crystal, ceruse, or sugar, became more luminous. He also tried the effects of it when poured upon various other substances, but there was nothing very remarkable in them. Afterwards, using luminous milk, he found that oil of vitriol extinguished the light, but that of tartar increased it.

This gentleman had the curiosity to try how differently-coloured substances were affected by this kind of light; and having, for this purpose, dipped several ribbons in it, the white came out the brightest, next to this was the yellow, and then the green; the other colours could hardly be perceived. It was not, however, any particular colour, but only light, that was perceived in this case. He then dipped boards painted with the different colours, and also glass tubes filled with substances of different colours, in water rendered luminous by the fishes. In both these cases, the red was hardly visible, the yellow was the brightest, and the violet the dullest. But on the boards, the blue was nearly equal to the yellow, and the green more languid; whereas in the glasses, the blue was inferior to the green.

Of all the liquors to which he put the phloades, milk was rendered the most luminous. A single phloas made seven ounces of milk so luminous, that the faces of persons might be distinguished by it, and it looked as if it was transparent.

Air appeared to be necessary to this light; for when Beccarius put the luminous milk into glass tubes, no agitation would make it shine unless bubbles of air were mixed with it. Also Montius and Galeatius found, that, in an exhausted receiver, the phloas lost its light, but the water was sometimes made more luminous; which they ascribed to the rising of bubbles of air through it.

Beccarius, as well as Reaumur, had many schemes to render the light of these phloades permanent. For this purpose he kneaded the juice into a kind of paste with flour, and found that it would give light when it was immersed in warm water; but it answered best to preserve the fish in honey. In any other method of preservation, the property of becoming luminous would not continue longer than six months, but in honey it had lasted above a year; and then it would, when plunged in warm water, give as much light as ever it had done.

PHLOMIS, the *sage-tree*, or *Jerusalem sage*, a genus of the gymnospermia order, in the didynamia class of plants. The calyx is angular; corolla, upper lip incumbent, compressed, villose. There are 22 species, all of which have perennial roots, and of many the stalks also are perennial. The latter rise from two to five or six feet high, and are adorned with yellow, blue, or purple flowers in whorls. They are all ornamental plants, and deserve a place in gardens or greenhouses. Some are sufficiently hardy to endure the ordinary winters in this climate, but they require a pretty warm situation.

PHLOX, *lychnidea*, or *bastard lychnis*, a genus of the monogynia order, in the pentandria class of plants. The corolla is salver-shaped; filam. unequal; stigma trifid; calyx prismatical; capsules three-celled, one-seeded. There are 12 species, all but one natives of North America. They have perennial roots, from which arise herbaceous stalks from nine inches to two feet in height, adorned with tubulated flowers of a white or purple colour. They are propagated by offsets, and will bear the winter in this country. They require a moist rich soil, in which they thrive better and grow taller than in any other.

PHOCA, *seal*, a genus of quadrupeds of the order feræ. The generic character is, fore-teeth in the upper jaw six, pointed, parallel, the exterior larger; in the lower jaw four, bluntish, parallel, distinct, equal; canine teeth one on each side in both jaws, large, pointed; the upper ones distinct from the cutting-teeth, the lower from the grinders; grinders five on each side above, six below, obtusely tricuspidated. This genus is marine. It is, however, so constituted as to require occasionally some intervals of repose, and even a considerable degree of continuance, on dry land; forsaking, at particular periods, the water, and congregating in vast multitudes on the shores, on floating ice, or on insulated rocks, especially during the season in which the young are produced. See AMPHIBIOUS. There are about 19 species, the most noted of which are:

1. Phoca vitulina, the common seal, is a native of the European seas, and is found about all the coasts of the northern hemisphere, and even extends as far as the opposite one, being seen in vast numbers about the southern polar regions. It also inhabits some fresh-water lakes, as that of Baikal, Oron, &c. and in these lakes it is considerably smaller, but much fatter, than when found in the sea.

The size of the seal varies, but its general length seems to be from five to six feet. The head is large and round, the neck small and short; on each side the mouth are situated several strong vibrissæ or whiskers, each hair being marked throughout its whole length with numerous alternate contractions and dilations. The parts about the shoulders and breast are very thick, and thence the body tapers towards the tail. The eyes are large; there are no external ears; the tongue is bifid or cleft at the tip. The legs are so very short as to be scarcely perceptible; and the hinder ones are so placed as to be only of use to the animal in swimming, or but very little to assist it in walking, being situated at the extremity of the body, and close to each other. All the feet are strongly webbed, but the hind ones much more widely and conspicuously than the fore. The toes on all the feet are five in number, and the claws are strong and sharp. The tail is very short. The whole animal is covered with short thick-set hair. In colour the seal varies considerably, being sometimes grey, sometimes brown or blackish, and sometimes variously patched or spotted with white or yellowish. When these animals collect together in great numbers on the shore, they diffuse a very strong and disagreeable smell.

Seals may often be observed sleeping on the tops of rocks, near the coast; but when approached they suddenly precipitate themselves into the water. Sometimes, however, their sleep is very profound, and it is even affirmed by some that the seal sleeps more profoundly than most other quadrupeds. The seal is possessed of a considerable degree of intelligence, and may be tamed, so as to become perfectly familiar with those to whose care it is committed, and even to exhibit several tricks and gesticulations. Of this we have numerous examples. The female seals produce their young in the winter season, and seldom bring more than two at a birth. It is said that they suckle the young for about the space of a fortnight on the spot where they were born, after which they take them out to sea, and instruct them in swimming and seeking for their food, which consists not only of fish, but of sea-weeds, &c. &c. When the young are fatigued, the parent is said to carry them on its back. The seal is supposed to be a long-lived animal, and Buffon is even inclined to suppose that it may attain to the age of a hundred years. The voice of a full-grown seal is a hoarse kind of sound, not unlike the barking of a dog: that of the young resembles the mewing of a kitten. They have, however, like most other quadrupeds, various inflections of voice, according to the passions with which they are inspired. They are said to delight in thunder-storms, and at such periods to sit on the rocks and contemplate with seeming delight the convulsions of the elements; in this respect differing widely from the terrestrial quadrupeds, which are extremely terrified at such times. Seals are generally very fat, and are hunted in the northern regions for the sake of their oil, which forms a great article of commerce: their skins also are much used for various œconomical purposes. See Plate Nat. Hist. fig. 333.

2. Phoca ursina, ursine seal. This is one of the larger seals, growing to the length of eight feet, and weighing eight hundred pounds. The female falls far short of the size and weight of the male. The length of the fore legs is about twenty-four inches, and they are less immersed in the body than those of other seals; the feet are formed with toes, but are covered with a naked skin, and have merely the rudiments of nails, giving them the appearance of a turtle's fin; the hind legs are twenty-two inches long, and are fixed to the body behind, but are capable of being brought quite forwards occasionally, so that the animal can rub its head with them; these feet are divided into five toes, separated by a large web, and are a foot broad: the tail is only two inches long. The hair is long and rough, and beneath it is a soft down of a bay colour; on the neck of the male the hair is upright, and a little longer than the rest. The general colour of the animal is black, but the hair of the old ones is tipped with grey, and

the females are cinereous. The flesh of the females and the young is said to resemble lamb, and the young are said to be as good as sucking pigs.

They live in families; each male has from eight to fifty females, whom he guards with the jealousy of an Eastern monarch. Though they lie by thousands on the shore, each family keeps itself separate from the rest, and is sometimes so numerous as to amount to above a hundred. The old animals which have been deserted by the females, are said to live apart, and are most excessively splenetic and quarrelsome. They are extremely fierce, and enormously fat. It sometimes happens that they approach or intrude upon each other's station, in which case a battle ensues between the two individuals; and they, in the conflict, disturb the repose of some of their neighbours, till in the end the discord becomes universal, and is in a manner spread through the whole shore. Exclusive of the contests between these solitary males, similar disagreements take place between those who live in a more social state, either from invading each others' seats, endeavouring to allure the females, or interfering in the disputes of their neighbours. These conflicts are very violent, and the wounds they receive are very deep, and resemble the cuts of a sabre. At the end of the fray they fling themselves into the sea to wash away the blood. They shew a great attachment to their young, and shew all the signs of the deepest concern on losing them.

The ursine seal is an inhabitant of the islands in the neighbourhood of Kamtschatka. In these islands they are seen from June to September, during which time they breed and educate their young. In September they are said to quit their stations, and to return, some to the Asiatic, and some to the American shore; but are generally confined to a space in those seas between lat. 50 and 56. They swim very swiftly, at the rate of seven miles an hour, and are very fierce and strong. They are said to be very tenacious of life, and to live a fortnight after receiving such wounds as would immediately destroy almost any other animal.

3. Phoca leonina, bottle-nosed seal. This species (in the male) is distinguished by its projecting snout, which hangs several inches over the lower jaw; the upper part consisting of a loose wrinkled skin, which the animal, when angry, has a power of inflating, so as to give the nose an arched or hooked appearance. It is a very large species, the male measuring twenty, and the female about eighteen feet in length. The feet are short: the hinder ones webbed in such a manner as to resemble a kind of fins.

In the British Museum is a tolerably well preserved skin of a female, which formerly belonged to the museum of the Royal Society. This species inhabits the seas about New Zealand, the island of Juan Fernandez, and the Falkland islands. In Juan Fernandez, during the breeding-season, viz. in June and July, they are seen in great numbers suckling their young on the shore. They bring two young at a birth; the females are observed to be excessively fierce during the time of rearing the young; towards evening both the male and female swim out a little way to sea, the female bearing the young on her back, which it is said the male frequently pushes off, in order to oblige them to exercise their swimming powers. On the arrival of these animals on the breeding-islands, they are said to be so excessively fat as to resemble skins of oil; the tremulous motion of the blubber being plainly perceivable beneath the skin. A single animal has been known to yield a butt of oil, and to be so full of blood that what has run out has filled two hogsheads. The flesh is eatable. Lord Anson's sailors ate it under the denomination of beef, to distinguish it from that of the seal, which they termed lamb.

4. Phoca jubata, sea lion, or leonine seal. This is so termed from the large and loose mane or floating hair with which the head and neck of the male are furnished. The nose is short and turns up a little, the eyes are large, the whiskers very large and strong, the hair on the whole body is smooth, short, and glossy, its colour is a deep brown; but those of this species which are found in Kamtschatka are said to be reddish, and the females tawny. The males are far larger than females, and grow from the length of from ten to fourteen feet; the females are from six to eight feet, and of a more slender form than the males. The weight of a full-grown male is from twelve to fifteen hundred pounds. A still greater size has been ascribed to those of Falkland isles, viz. that of twenty-five feet in length, and nineteen or twenty feet round the shoulders.

These animals inhabit, in vast numbers, the islands called Penguin and Seal islands, near Cape Desire, on the coast of Patagonia; and are found within the Magellanic straits, and on Falkland islands, but have not been discovered in any other part of the southern hemisphere, nor in any other place nearer than the sea between Kamtschatka and America. They live in families distinct from the ursine and other seals; their manners, however, are nearly the same; they are polygamous, each male being accompanied by from two to thirty females. The males utter a snorting sound, and occasionally roar like bulls; the voice of the females resembles that of calves, and the young bleat like lambs. The food of the leonine seal consists of the smaller kinds of penguins, fish, seals, &c. but during the breeding-season they are said to fast for three or four months, during which time they swallow a number of large stones, in order to keep their stomachs in a distended state.

5. Phoca lupina, urigne seal. This is a smaller species than the former, being found from about three to eight feet in length. The body is thick at the shoulders, and gradually lessens to the hind legs. The head resembles that of a dog with close-cut ears; the nose is short and blunt; in the mouth are six cutting teeth above, and four below; the fore feet have four toes inclosed in a membranaceous sheath, so as to resemble fins; and the hind feet are hid in a continuation of the skin of the back, and have five toes of unequal length like the fingers of the human hand; the tail is three inches long; the skin is covered with two sorts of hair, one like that of an ox, the other harder; the colours are various. These animals are the sea-wolves mentioned by navigators off the island of Lobos near the river Plata. They are said to appear there in vast multitudes, and to meet the ships, and even to hang at the ship's side by their paws, seeming to stare at and admire the crew, then drop off and return to their former haunts. The natives of Chili kill them for the sake of their oil.

PHŒNICOPTERUS, or Flamingo, in ornithology, a genus of birds belonging to the order of grallæ. The beak is naked, teethed, and bent, as if it was broken; the nostrils are linear; the feet are palmated, and four-toed. There is but one species, viz. the bahamensis of Catesby, a native of Africa and America.

This bird resembles the heron in shape, excepting the bill, which is of a very singular form. It is two years old before it arrives at its perfect colour, and then it is entirely red, excepting the quill-feathers, which are black. A full-grown one is of equal weight with a wild duck; and when it stands erect, it is five feet high. The feet are webbed. The flesh is delicate, and most resembles that of a partridge in taste. The tongue, above any other part, was in the highest esteem with the luxurious Romans. These birds make their nests on hillocks in shallow water, on which they sit with their legs extended down, like a man sitting on a stool. They breed on the coasts of Cuba and the Bahama islands in the West Indies, and frequent salt water only. From the particular shape of its bill, this bird, in eating, twists its neck from side to side, and makes the upper mandible touch the ground. They are very stupid, and will not rise at the report of a gun; nor is it any warning to those who survive that they see others killed by their side; so that, by keeping himself out of sight, a fowler may kill as many as he pleases.

These birds prefer a warm climate. In the old continent they are not often met with beyond 40 degrees north or south. They are met with every where on the African coast and adjacent isles, to the Cape of Good Hope: and sometimes on the coasts of Spain, Italy, and those of France lying in the Mediterranean sea; being at times found at Marseilles, and for some way up the Rhone. In some seasons they frequent Aleppo and the parts adjacent. They are seen also on the Persian side of the Caspian Sea, and thence along the western coast as far as the Wolga; though this is at uncertain times, and chiefly in considerable flocks coming from the north-east, mostly in October and November; but as soon as the wind changes they totally disappear. They breed in the Cape Verd isles, particularly that of Sal. They go for the most part together in flocks, except in breeding time. They are very numerous at the Cape; keeping in the day on the borders of the lakes and rivers, and lodging themselves at night in the long grass on the hills. They are also common to various places in the warmer parts of America, frequenting the same latitudes as in other quarters of the world; being found at Peru, Chili, Cayenne, and the coast of Brasil, as well as the various islands of the West Indies. Sloane found them in Jamaica. When seen at a distance, they appear as a regiment of soldiers, being ranged alongside one another, on the borders of the rivers, searching for food, which chiefly consists of small fish, or the eggs of them; and of water-insects, which they search after by plunging in the bill and part of the head, from time to time trampling with their feet to muddy the water, that their prey may be raised from the bottom. Whilst they are feeding, one of them is said to stand sentinel, and the moment he sounds the alarm, the whole flock takes wing. This bird, when at rest, stands on one leg, the other being drawn up close to the body, with the head placed under the wing on that side of the body it stands on. See Plate Nat. Hist. fig. 332.

They are sometimes caught young, and are brought up tame; but are always impatient of cold; and in this state will seldom live a great while, gradually losing their colour, flesh, and appetite, and dying for want of that food which in a state of nature at large they were abundantly supplied with.

PHŒNIX, in astronomy, one of the constellations of the southern hemisphere, unknown to the antients, and invisible in our northern parts. See ASTRONOMY.

PHŒNIX, the *great palm* or *date-tree*, a genus of plants belonging to the order palmæ. The calyx is 3-parted; corolla 3-petalled; male stamina three; female pist. one, drupe ovate. There is only species, viz. the dactylifera, or common date-tree, a native of Africa and the Eastern countries, where it grows to 50, 60, and 100 feet high. The trunk is round, upright, and studded with protuberances, which are the vestiges of the decayed leaves. From the top issues forth a cluster of leaves or branches eight or nine feet long, extending all round like an umbrella, and bending a little towards the earth. The bottom part produces a number of stalks like those of the middle, but seldom shooting so high as four or five feet. These stalks, says Adanson, diffuse the tree very considerably; so that wherever it naturally grows in forests, it is extremely difficult to open a passage through its prickly leaves. The date-tree was introduced into Jamaica soon after the conquest of the island by the Spaniards. There are, however, but few of them in Jamaica at this time. The fruit is somewhat in the shape of an acorn. It is composed of a thin, light, and glossy membrane, somewhat pellucid and yellowish, which contains a fine, soft, and pulpy fruit, which is firm, sweet, and somewhat vinous to the taste, esculent, and wholesome; and within this is enclosed a solid, tough, and hard kernel, of a pale grey colour on the outside, and finely marbled within like the nutmeg. The best are brought from Tunis: they are also very fine and good in Egypt, and in many parts of the East. Those of Spain and France look well; but are never perfectly ripe, and very subject to decay. Dates have always been esteemed moderately strengthening and astringent.

Though the date-tree grows every where indiscriminately on the northern coasts of Africe, it is not cultivated with care, except beyond mount Atlas; because the heat is not sufficiently powerful along the coasts to bring the fruits to proper maturity. We shall here extract some observations from M. Des Fontaines respecting the manner of cultivating it in Barbary, and on the different uses to which it is applied. All that part of the Zaara, which is near mount Atlas, and the only part of this vast desert which is inhabited, produces very little corn; the soil being sandy, and burnt up by the sun, is almost entirely unfit for the cultivation of grain, its only productions of that kind being a little barley, maize, and sorgo. The date-tree, however, supplies the deficiency of corn to the inhabitants of these countries, and furnishes them with almost the whole of their subsistence. They have flocks of sheep; but as they are not numerous, they preserve them for the sake of their wool; besides, the flesh of these animals is very unwholesome food in countries that are excessively warm; and these people, though ignorant, have probably been enabled by experience to know that it was salutary for them to abstain from it. The date-trees are planted without any order, at the distance of 12 feet one from the other, in the neighbourhood of rivulets and streams, which issue from the sand. Forests of them may be seen here and there, some of which are several leagues in circumference. The extent of these plantations depends upon the quantity of water which can be procured to water them, for they require much moisture. All these forests are intermixed with orange, almond, and pomegranate trees, and with vines which twist round the trunks of the date-trees; and the heat is strong enough to ripen the fruit, though they are never exposed to the sun.

It is generally in winter that new plantations of this tree are formed. For this purpose those who cultivate them take shoots of those which produce the best dates, and plant them at a small distance one from the other. At the end of three or four years, these shoots, if they have been properly taken care of, begin to bear fruit: but this fruit is as yet dry, without sweetness, and even without kernels; they never reach the highest degree of perfection of which they are susceptible till they are about 15 or 20 years old.

These plants are, however, produced from the seeds taken out of the fruit, provided they are fresh. They should be sown in pots filled with light rich earth, and plunged into a moderate hot-bed of tanner's bark, which should be kept in a moderate temperature of heat, and the earth frequently refreshed with water. When the plants are come up to a proper size, they should be each planted in a separate small pot, filled with the same light earth, and plunged into a hot-bed again; observing to refresh them with water, as also to let them have air in proportion to the warmth of the season, and the bed in which they are placed. During the summer time they should remain in the same hot-bed; but in the beginning of August they should have a great share of air to harden them against the approach of winter; for if they are too much forced, they will be so tender as not to be preserved through the winter without much difficulty, especially if you have not the conveniency of a bark-stove to keep them in.

The trees, however, which spring from seed, never produce so good dates as those that are raised from shoots, they being always poor and ill-tasted. It is undoubtedly by force of cultivation, and after several generations, that they acquire a good quality. The date-trees which have been originally sown grow rapidly, and we have been assured that they bear fruit in the fourth or fifth year. Care is taken to cut the inferior branches of the date-tree in proportion as they rise; and a piece of the root is always left of some inches in length, which affords the easy means of climbing to the summit. These trees live a long time, according to the account of the Arabs; and in order to prove it, they say that when they have attained to their full growth, no change is observed in them for the space of three generations.

The number of females which are cultivated is much superior to that of the males, because they are much more profitable. The sexual organs of the date-tree grow, as is well known, upon different stalks, and these trees flower in the months of April and May, at which time the Arabs cut the male branches to impregnate the female. For this purpose they make an incision in the trunk of each branch which they wish to produce fruit, and place in it a stalk of male flowers; without this precaution the date-tree would produce only abortive fruit. In some cantons the male branches are only shaken over the female. The practice of impregnating the date-tree in this manner is very antient. Pliny describes it very accurately in that part of his work where he treats of the palm-tree.

There is scarcely any part of the date-tree which is not useful. The wood, though of a spungy texture, lasts such a number of years, that the inhabitants of the country say it is incorruptible. They employ it for making beams and instruments of husbandry; it burns slowly, but the coals which result from its combustion are very strong, and produce a great heat.

The Arabs strip the bark and fibrous parts from the young date-trees, and eat the substance, which is in the centre; it is very nourishing, and has a sweet taste: it is known by the name of the marrow of the date-tree. They eat also the leaves, when they are young and tender, with lemon-juice; the old ones are laid out to dry, and are employed for making mats and other works of the same kind, which are much used, and with which they carry on a considerable trade in the interior parts of the country. From the sides of the stumps of the branches which have been left, arise a great number of delicate filaments, of which they make ropes, and which might serve to fabricate cloth.

A white liquor, known by the name of milk, is drawn also from the date-tree. To obtain it, all the branches are cut from the summit of one of these trees, and after several incisions have been made in it, they are covered with leaves, in order that the heat of the sun may not dry it. The sap drops down into a vessel placed to receive it, at the bottom of a circular groove made below the incisions. The milk of the date-tree has a sweet and agreeable taste when it is new; it is very refreshing, and is even given to sick people to drink, but it generally turns sour at the end of 24 hours. Old trees are chosen for this operation, because the cutting of the branches, and the large quantity of sap which flows from them, greatly exhaust them, and often cause them to decay.

The male flowers of the date-tree are also useful. They are eaten when still tender, mixed up with a little lemon-juice. They are reckoned to be very provocative; the odour which they exhale is probably the cause of this property being ascribed to them. These date-trees are very lucrative to the inhabitants of the desert. Some of them produce 20 bunches of dates; but care is always taken to lop off a part of them, that those which remain may become larger; 10 or 12 bunches only are left on the most vigorous trees. It is reckoned that a good tree produces, one year with another, about the value of 10 or 12 shillings to the proprietor. A pretty considerable trade is carried on with dates in the interior part of the country, and large quantities of them are exported to France and Italy. The crop is gathered towards the end of November. When the bunches are taken from the tree, they are hung up in some very dry place where they may be sheltered and secure from insects.

Even the stones, though very hard, are not thrown away. They give them to their camels and sheep as food, after they have bruised them or laid them to soften in water.

The date, as well as other trees which are cultivated, exhibits great variety in its fruit, with respect to shape, size, quality, and even colour. There are reckoned to be at least 20 different varieties. Dates are very liable to be pierced by worms, and they soon corrupt in moist or rainy weather.

From what has been said, it may easily be perceived that there is, perhaps, no tree whatever used for so many and so valuable purposes as the date-tree.

PHORMIUM, *flax-plant*, a genus of the class and order hexandria monogynia. There is no calyx; the corolla is six-petalled, three inner larger; capsule oblong, three-sided; seeds oblong, compressed. Of this plant there is one species: the leaves resemble those of flags; the flowers are in one variety yellow, and in the other a deep red. Of the leaves of these plants, with very little preparation, the New Zealanders make all their common apparel, and also their strings, lines, and cordage, for every purpose; which are so much stronger than any thing we can make with hemp, that they will not bear a comparison. From the same plant, by another preparation, they draw long slender fibres, which shine like silk, and are as white as snow. Of these, which are very strong, they make their finest cloths; and of the leaves, without any other preparation than splitting them into proper breadths, and tying the strips together, they make their fishing-nets, some of which are of an enormous size. The seeds of this valuable plant have been brought over into England; but upon trial appeared to have lost their vegetating power.

PHOSPHATS, salts formed by the phosphoric acid, with the alkalies, earths, and metallic oxides. They may be distinguished by the following properties: (1.) When heated with combustibles, they are not decomposed, nor is phosphorus obtained. (2.) Before the blowpipe they are converted into a globule of glass, which in some cases is transparent, in others opaque. (3.) Soluble in nitric acid without effervescence, and precipitated from that solution by lime-water. (4.) Decomposed, at least partially, by sulphuric acid; and their acid, which is separated, when mixed with charcoal and heated to redness, yields phosphorus. (5.) After being strongly heated, they often phosphoresce.

The phosphats readily combine with an excess of acid, and form superphosphats.

The phosphats at present known amount to 12; two of which are triple salts. Some of these salts occur in different states, constituting varieties.

Phosphat of barytes. It may be prepared either by saturating phosphoric acid with barytes or carbonat of of barytes, or by mixing together an alkaline phosphat and nitrat or muriat of barytes. In either case the phosphat of barytes precipitates immediately in the form of a white powder.

This salt is tasteless, incrystallizable by art, insoluble in water, and not altered by exposure to the air. Its specific gravity is 1.2867. When strongly heated, it melts into a grey-coloured enamel. The proportion of its component parts is unknown.

This salt has not been applied to any use.

When phosphoric acid is dropt into a solution of barytes-water, a precipitate of phosphat of barytes immediately falls. But this precipitate is redissolved by adding an excess of acid. Hence it follows, that this salt is capable of combining with an additional dose of acid, and forming a superphosphat of barytes.

Phosphat of strontian. Like the former, it may be formed by dissolving carbonat of strontian in phosphoric acid, or by mixing together nitrat of strontian and phosphat of soda. A white precipitate immediately falls, which is the phosphat of strontian.

This salt is tasteless, insoluble in water, and not alterable by exposure to the air. It is soluble in an excess of phosphoric acid; a property which distinguishes it from phosphat of barytes. Before the blowpipe it fuses into a white enamel, and at the same time emits a phosphoric light. It is completely decomposed by sulphuric acid, but by no other. According to Vauquelin, it is composed of

41.24	acid
58.76	strontian.
100.00	

Phosphat of lime. Of this salt there are two varieties, the first neutral, the other a supersalt.

1. Phosphat of lime. As this salt constitutes the basis of bones, it is not necessary to prepare it artificially. It may be obtained in a state of purity by the following process: Calcine the bones to whiteness, reduce them to powder, and wash them repeatedly with water, to separate several soluble salts which are present. Dissolve the whole in muriatic acid, and precipitate by means of ammonia. The precipitate, when well washed and dried, is pure phosphat of lime.

Phosphat of lime, thus prepared, is always in the state of a white powder; but it is found native in regular crystals. In that state it is known by the name of apatite. The primitive form of its crystals is, according to Hauy, the regular six-sided prism; and the primitive form of its integrant particles is a three-sided prism, whose bases are equilateral triangles: but it very often assumes other forms. It is destitute of taste, insoluble in water, and not liable to be altered by exposure to the air. It may be exposed to a strong heat without undergoing any change; but in a very violent heat it becomes soft, and is converted into a white semitransparent enamel, or rather porcelain. According to the experiments of Saussure, a heat of 378° Wedgewood is necessary to produce this effect.

Sulphuric, nitric, muriatic, fluoric, and several vegetable acids, are capable of decomposing phosphat of lime; but the decomposition is only partial. Fourcroy and Vauquelin have ascertained, that these acids are only capable of abstracting 0.40 parts of the lime, while the remainder continues combined with the phosphoric acid, constituting a superphosphat of lime. Hence the reason that phosphoric acid is capable also of decomposing partially the combinations of these acids with lime; it abstracts as much of the lime as is sufficient to convert it into superphosphat. Phosphat of lime, according to Fourcroy and Vauquelin, is composed of

41	acid
59	lime
100.	

2. Superphosphat of lime. It is this salt which always remains in the aqueous solution when calcined bones are decomposed by means of sulphuric acid; and it may be formed artificially by dissolving phosphat of lime in phosphoric acid, till the acid refuses to take up any more, and afterwards evaporating the solution till the salt crystallizes. Its crystals are usually thin brilliant plates, resembling mother-of-pearl, which easily adhere together, and acquire a kind of gluey consistency. Its taste is strongly acid. Water dissolves it, and in a greater proportion when boiling-hot than when cold Hence a saturated solution of it in boiling water crystallizes on cooling. It attracts a little moisture when exposed to the air. When heated, it readily undergoes the watery fusion, then swells up and dries. In a high temperature it melts into a semitransparent glass, which is tasteless and insoluble, and is not altered by exposure to the air. When this salt is heated to redness along with charcoal, its excess of acid is decomposed, and converted into phosphorus, and phosphat of lime remains behind. It is from this salt that phosphorus is usually obtained; but the process of Fourcroy, which consists in decomposing the superphosphat of lime by means of acetat of lead, and afterwards decomposing the phosphat of lead by means of charcoal, must yield a much greater proportion of phosphorus.

No acid hitherto tried is capable of decomposing this salt, except the oxalic, which abstracts its base completely, and precipitates with it in the form of oxalat of lime; but it is decomposed and reduced to the state of phosphat of lime by all the alkaline and earthy bases. It is composed, according to the analysis of Fourcroy and Vauquelin, of

54	acid
46	lime
100.	

Phosphat of potass. Of this salt there are two varieties: the first, which contains an excess of acid, and is in reality a superphosphat, has been long known, and appears to have been first mentioned by Lavoisier in 1774; but it is to Vauquelin that we are indebted for an examination of its properties. The second, which is a neutral salt, was lately discovered by Darracq. It had been formed indeed previously by Guyton Morveau and Desormes; but these gentlemen had mistaken it for phosphat of lime.

1. Superphosphat of potass is prepared by dropping carbonat of potass into phosphoric acid till all effervescence ceases, and then evaporating to the proper consistency. It does not crystallize. When evaporated sufficiently, it assumes the form of a jelly; and if the evaporation is carried farther, it becomes dry altogether. Its specific gravity, when dry, is 2.85. It is exceedingly soluble in water, and when dry readily attracts moisture

from the atmosphere, and is converted into a viscid liquid. When heated, it first undergoes the watery fusion; then allows its water of crystallization to evaporate, and is reduced to dryness. In a high temperature it melts into a transparent glass, which deliquesces again when exposed to the air.

It is completely decomposed by the sulphuric, nitric, and muriatic acids; and by barytes, strontian, and lime.

2. Phosphat of potass. This salt may be formed by mixing together superphosphat of potass and pure potass, and exposing them to a strong heat in a platinum crucible. A white-coloured substance is obtained, which is the phosphat in question. This salt is tasteless and insoluble in cold water, but soluble in hot water, and it precipitates as the solution cools in a gritty brilliant powder. It is extremely fusible; melting before the blowpipe into a transparent bead, which becomes opaque on cooling. It is soluble in nitric, muriatic, and phosphoric acids: the solutions are thick, glutinous, and adhesive. When sufficiently diluted, the alkalies occasion no precipitate in these solutions; but when they are concentrated, a precipitate appears.

Phosphat of soda. This salt exists ready-formed in urine, and was the first known of all the phosphats. It occupied a good deal of the attention of chemists; and the difficulty of analysing it gave occasion to various hypotheses concerning its nature. Hellot remarked it in urine; and described it in 1737, as a salt different from those that had usually been observed. Haupt described it in 1740 under the name of sal mirabile perlatum, or "wonderful perlated salt." It was called perlated from the grey, opaque, pearl-like colour, which it assumed when melted by the blowpipe. Margraff examined it in 1745, and found it would not yield phosphorus when treated with charcoal, as the other salts of urine did.

Dr. Pearson afterwards introduced it with great advantage into medicine as a purgative. He gives the following process for preparing it: Dissolve, in a long-necked matrass, 1400 grains of crystallized carbonat of soda, in 2100 grains of water at the temperature of 150°. Add gradually 500 grains of phosphoric acid of the specific gravity 1.85. Boil the liquor for some minutes; and while it is boiling-hot, filtrate it, and pour it into a shallow vessel. Let it remain in a cool place, and crystals will continue to form for several days. From the above quantities of materials he has obtained from 1450 to 1550 grains of crystals.

Its crystals are rhomboidal prisms, of which the acute angles are 60°, and the obtuse angles 120°, terminated by a three-sided pyramid. Its specific gravity is 1.333. Its taste is almost the same with that of common salt. It is soluble at the temperature of 60° in about four parts of water, and in two parts of boiling water. This solution crystallizes on cooling; but in order to obtain the salt properly crystallized, the solution should contain a slight excess of alkali. When exposed to the air, this salt very soon effloresces on the surface. When heated, it undergoes the watery fusion. At a red heat it melts into a white enamel. Before the blowpipe it melts into a transparent globule, which becomes opaque on cooling, and its surface acquires a polyhedral figure. It is not altered by combustibles nor metals. With metallic oxides it enters into fusion, and forms a coloured globule of glass. Sulphuric, nitric, and muriatic acids, decompose it partially, and convert it into superphosphat of soda. In this state it is more soluble in water, and not so easily crystallized; but may be obtained, by proper evaporation, in the state of thin scales, not unlike boracic acid.

The greater number of earths may be fused along with this salt, and converted into glass.

This salt has been applied to various uses. It has been introduced into medicine as a purgative, and on account of its pleasant taste has of late been much used. It is usually taken in broth, which it is employed to season instead of common salt. It may be substituted for borax to promote the soldering of metals. Mineralogists employ it very much as a flux when they examine the action of heat on minerals by means of the blowpipe.

Phosphat of ammonia. It exists also in urine, and seems to have been first accurately distinguished by Rouelle. It is usually prepared by saturating with ammonia the superphosphat of lime obtained from bones, and evaporating the solution to such a consistency, that when allowed to cool, the phosphat of ammonia is obtained in crystals.

It crystallizes in four-sided prisms, terminated by equal-sided pyramids. Its taste is cooling, salt, and ammoniacal. Its specific gravity is 1.80. It is soluble in four parts of water at the temperature of 60°, and in rather a smaller proportion of boiling water. It is by spontaneous evaporation that it is obtained in the state of regular crystals. It is not altered by exposure to the air. When heated, it undergoes the watery fusion; it then dries; but if the heat is continued, it swells up, loses its alkaline base, and the acid melts into a transparent glass. It is the only one of the earthy and alkaline phosphats which can be decomposed by heat. Hence the reason that it yields phosphorus when distilled along with charcoal.

It is decomposed by the sulphuric, nitric, and muriatic acids, and by the fixed alkalies and alkaline earths. It is capable of combining with an additional dose of acid, and of passing into the state of a superphosphat.

This salt is much employed as a flux in experiments with the blowpipe. It enters also as an ingredient in those coloured glasses called pastes, which are made in imitation of precious stones.

Phosphat of magnesia. It is usually prepared by dissolving carbonat of magnesia in phosphoric acid, and evaporating the solution gradually till the salt crystallizes; but it may be obtained in large regular crystals by a much easier process. Mix together equal parts of the aqueous solutions of phosphat of soda and sulphat of magnesia. No apparent change takes place at first; but in a few hours large transparent crystals of phosphat of magnesia make their appearance in the solution.

Its crystals are six-sided prisms, the sides of which are unequal. It has very little taste; however, it leaves a cooling and sweetish impression upon the tongue. Its specific gravity is 1.55. It requires about 15 parts of cold water to dissolve it. It is more soluble in boiling water, but it crystallizes in part as the solution cools. When exposed to the air it loses its water of crystallization, and falls down in powder. When heated moderately, it is also reduced to a dry powder. In a high temperature it melts into a transparent glass.

Phosphat of glucina. It is obtained by pouring phosphat of soda into the solution of glucina in sulphuric, nitric, or muriatic acids. The phosphat of glucina is precipitated in the state of a white powder. It does not crystallize. It is tasteless, insoluble in water unless it contains an excess of acid, and not liable to be altered by exposure to the air. When heated strongly, it melts into a transparent glass.

Phosphat of yttria. When the solution of phosphat of soda is mixed with the sulphat, nitrat, or muriat of yttria, phosphat of yttria precipitates in gelatinous flakes.

Phosphat of alumina. It may be formed by saturating phosphoric acid with alumina. It is a tasteless powder, insoluble in water. Dissolved in phosphoric acid it yields a gritty powder, and a gummy solution, which by heat is converted into a transparent glass.

Phosphat of soda and ammonia, known to chemists by the names of microcosmic salt, and fusible salt of urine, was extracted from urine, and examined, much sooner than any of the other phosphats: it was long before philosophers were able to form precise notions concerning its nature, or even to obtain it in a state of purity. This indeed could not be expected till the phosphats of soda and of ammonia had been accurately examined, and their composition ascertained. Fourcroy was the first who gave a precise account of the proportion of its component parts. According to him, it is composed of

32	acid
24	soda
19	ammonia
25	water
100.	

The properties of this salt are nearly those of the phosphat of soda and phosphat of ammonia joined together. It answers better than the first of them as a flux; because the heat soon drives off the ammonia, and leaves an excess of acid. Its specific gravity is 1.5. When exposed to the air, this salt effloresces, and gradually loses its ammonia.

Phosphat of ammonia and magnesia was first discovered by Fourcroy, who found it in a calculous concretion formed in the colon of a horse. Since this discovery Fourcroy and Vauquelin have observed it also in human urine.

It might be prepared by mixing together solutions of the phosphats of ammonia and of magnesia in water; the triple salt immediately precipitates in the state of a white powder. When urine is allowed to remain a considerable time in close vessels, it often deposits this salt in regular crystals on the sides and bottom of the vessel. These crystals are small four-sided prisms, terminated by irregular four-sided pyramids. This salt is tasteless, scarcely soluble in water, and not liable to be altered by exposure to the air. When heated it falls to powder, gives out its ammonia, and in a high temperature melts into a transparent globule. It is composed of

33 phosphat of ammonia
33 phosphat of magnesia
33 water

99.

Phosphoric acid and silica, when mixed together and exposed to a strong heat, melt into a beautiful transparent glass, which is not decomposed either by the action of acids or of alkalies. Fourcroy has given this compound the name of phosphat of silica; but it is essentially different from salts, and ought therefore rather to be ranked among some other class of bodies.

PHOSPHITES, salts formed with the phosphorous acid united to the earths, alkalies, and metallic oxides. These salts may be distinguished by the following properties: 1. When heated they emit a phosphorescent flame. 2. When distilled in a strong heat, they give out a little phosphorus, and are converted into phosphats. 3. They detonate when heated with nitrat or oxymuriat of potass, and are converted into phosphats. 4. They may be converted into phosphats by nitric and oxymuriatic acid. 5. They are fusible in a violent heat into glass.

The phosphites at present known amount to eight:

1. Phosphite of lime. This salt may be formed by dissolving lime in phosphorous acid. When the saturation is complete, the salt precipitates in the state of a white powder. It is tasteless and insoluble in water; but it dissolves in an excess of acid, and forms a superphosphite. This last salt may be obtained in prismatic crystals by evaporating the solution. It is not altered by exposure to the air. When heated, it phosphoresces and emits a little phosphorus. In a violent heat, it melts into a transparent globule.

It is composed of 34 acid
51 lime
15 water

100.

2. Phosphite of barytes may be formed by pouring phosphorous acid into barytes water, or this last water into a solution of phosphite of soda. In either case phosphite of barytes precipitates in the form of a white powder. It is tasteless, and but very sparingly soluble in water, unless there is an excess of acid. It is not altered by exposure to the air. Before the blowpipe it melts, and is surrounded with a light so brilliant that the eye can scarcely bear it. The globule which it forms becomes opaque as it cools.

It is composed of 41.7 acid
51.3 barytes
7.0 water.

100.0

3. Phosphite of magnesia is best formed by mixing together aqueous solutions of phosphite of potass or soda and sulphat of magnesia; the phosphite of magnesia gradually precipitates in beautiful white flakes. It has no sensible taste. It is soluble in 400 parts of water at the temperature of 60°, and scarcely more soluble in boiling water. When its solution is evaporated slowly, a transparent pellicle forms on its surface, flakes are deposited, and towards the end of the process small tetrahedral crystals are precipitated. When exposed to the air it effloresces. When heated it phosphoresces and melts into a glass, which becomes opaque on cooling.

It is composed of 44 acid
20 magnesia
36 water

100.

4. Phosphite of potass. This salt is formed by dissolving carbonat of potass in phosphorous acid, and evaporating the solution slowly till it deposits crystals of phosphite of potass. It crystallizes in four-sided rectangular prisms, terminated by dihedral summits. Its taste is sharp and saline. It is soluble in three parts of cold water, and still more soluble in boiling water. It is not altered by exposure to the air. When heated, it decrepitates, and then melts into a transparent globule, which becomes opaque on cooling. It does not phosphoresce so evidently as the other phosphites, perhaps because it contains an excess of potass, which saturates the phosphoric acid as it forms.

It is composed of 39.5 acid
49.5 potass
11.0 water.

100.0

5. Phosphat of soda may be prepared exactly in the same way as phosphite of potass. Its crystals are irregular four-sided prisms or elongated rhomboids. Sometimes it assumes the form of square plates, or of plumose crystals. Its taste is cooling and agreeable. It is soluble in two parts of cold water, and scarcely more soluble in boiling water. When exposed to the air it effloresces. Before the blowpipe it emits a beautiful yellow flame, and melts into a globule, which becomes opaque on cooling.

It is composed of 16.3 acid
23.7 soda
60.0 water.

100.0

6. Phosphite of ammonia may be prepared by the same processes as the two last-described phosphites. It crystallizes sometimes in long transparent needles, and sometimes in four-sided prisms terminated by four-sided pyramids. It has a very sharp saline taste. It is soluble in two parts of water at the temperature of 60°, and still more soluble in boiling water. When exposed to the air, it attracts moisture, and becomes slightly deliquescent. When distilled in a retort, the ammonia is disengaged partly liquid and partly in the state of gas, holding phosphorus in solution, which becomes luminous when mixed with oxygen gas. Before the blowpipe on charcoal, it boils, and loses its water of crystallization; it becomes surrounded with a phosphorescent light; and bubbles of phosphureted hydrogen gas are emitted, which burn in the air with a lively flame, and form a fine coronet of phosphoric acid vapour. This gas is emitted also when the salt is heated in a small glass bulb, the tube belonging to which is plunged under mercury.

This salt is composed of 26 acid
51 ammonia
23 water

100.

7. Phosphite of ammonia and magnesia. This salt may be formed by mixing together the aqueous solutions of its two component parts. It is sparingly soluble in water, and may be obtained in crystals; but its properties have not been examined with precision.

8. Phosphite of alumina may be prepared by saturating phosphorous acid with alumina, and then evaporating the solution to a proper consistence. It does not crystallize, but forms a glutinous mass, which dries gradually, and does not afterwards attract moisture from the air. Its taste is astringent. It is very soluble in water. When heated, it froths and gives out phosphorus, but it does not readily melt into a globule of glass.

PHOSPHORIC ACID. Phosphorus forms an acid with two different proportions of oxygen: combined with the largest portion of oxygen, it constitutes phosphoric acid, and with the smaller it constitutes phosphorous acid.

1. It may be formed by setting fire to a quantity of phosphorus contained in a vessel filled with oxygen gas. The phosphorus burns with great rapidity, and a great number of white flakes are deposited, which are phosphoric acid in a state of purity. It may be obtained too by heating phosphorus under water till it melts, and then causing a stream of oxygen gas to pass through it by means of a tube. In this case the acid as it forms combines with the water; but the liquid may be evaporated off by the application of heat, and then the acid remains behind in a state of purity. But the usual method of procuring it is, to throw phosphorus in small pieces at a time into hot nitric acid. A violent effervescence takes place, the phosphorus combines with oxygen, and nitrous gas is emitted. After the whole of the phosphorus is acidified, the liquid is to be evaporated to dryness, in order to drive off the remains of nitric acid which may not have been decomposed. This process was first put in practice by Lavoisier. Care must be taken not to apply too much heat, nor to add too much phosphorus at once, and not to have the nitric acid too strong; otherwise the phosphorus takes fire, and usually breaks the vessels in pieces.

2. The acid, thus prepared, may be put into a platinum crucible, and heated to redness to drive off all the water. It is then in a state of purity. It is solid, colourless, and transparent, and not unlike glass in appearance. It reddens vegetable blues; it has no smell: its taste is very acid, but it does not destroy the texture of organic bodies.

When exposed to the open air, it soon attracts moisture, and deliquesces into a thick oily-like liquid, in which state it is usually kept by chemists. When exposed to the fire in a platinum crucible, its water gradually evaporates, and leaves it in the state of a transparent jelly. If the heat is increased it boils and bubbles up, owing to the separation of the remainder of its water accompanied with a small portion of acid. At a red heat it remains in the form of a transparent liquid, and when cooled assumes the form of the purest crystal. In this state it is known by the name of phosphoric glass. This glass is merely phosphoric acid totally deprived of water: It has an acid taste, is soluble in water, and deliquesces when exposed to the air.

The specific gravity of this acid, in a state of dryness, is 2.687; in the state of glass 2.85; in the state of deliquescence 14.

3. This acid is very soluble in water. When in the state of white flakes, it dissolves with a hissing noise similar to that made by red-hot iron plunged into water. When in the state of glass it dissolves much more slowly. The heat evolved during the combination of this acid and water, is much inferior to that evolved when sulphuric acid enters into a similar combination. Phosphoric acid obtained by deliquescence, when mixed with an equal quantity of distilled water, acquired so little heat as to raise the thermometer only one degree, as Mr. Sage observed. Mr. Lavoisier raised the thermometer from 50° to 63°, by mixing phosphoric acid boiled to the consistence of a syrup with an equal quantity of water; and from 50° to 104° when the acid was as thick as turpentine.

4. Oxygen gas has no action on phosphoric acid, whatever is the temperature. Neither is it decomposed or altered by any of the simple combustibles, if we except charcoal; which, though it has no action on it while cold, at a red heat decomposes it completely; carbonic acid is formed, and phosphorus sublimed. This is the common process for obtaining phosphorus.

5. Neither of the simple incombustibles has any particular action on it.

6. This acid, when in a liquid state, is capable of oxidizing some of the metals, especially when assisted by heat; at the same time hydrogen gas is emitted. Hence we see that the oxidizement is owing to the decomposition of water. In this manner it oxidizes iron, tin, lead, zinc, antimony, bismuth, manganese; but on some of these it acts very slowly. When fused with several of these metals, as tin, iron, and zinc, it is converted into phosphorus; a proof that they have a stronger affinity for oxygen.

It does not act upon gold, platinum, silver, copper, mercury, arsenic, cobalt, nickel. It appears, however, to have some action on gold in the dry way, as it is called; for when fused with gold-leaf it assumes a purple colour, a proof that the gold has been oxidized.

7. Phosphoric acid combines with alkalies, earths, and metallic oxides, and forms with them salts known by the name of phosphats.

8. Its affinities are as follow:

Barytes,
Strontian,
Lime,
Potass,
Soda,
Ammonia,
Magnesia,
Glucina,
Alumina,
Zirconia,
Metallic oxides,
Silica.

9. The component parts of this acid have been ascertained in a more satisfactory manner than almost any other chemical compound. Mr. Lavoisier proved, that 45 parts of phosphorus, when burnt in oxygen, absorbed about 69.375 parts of that gas, and produced about 114 parts of phosphoric acid Hence it follows that this acid is composed of about

60	oxygen
40	phosphorus
100,	

or 3 parts oxygen to 2 parts of phosphorus.

This acid is too expensive to be brought into common use. If it could be procured at a cheap rate, it might be employed with advantage, not only in several important chemical manufactures, but also in medicine, and perhaps even in domestic economy.

PHOSPHOROUS ACID: the acid obtained by the burning of phosphorus differs according to the rapidity of the combustion; or, which is the same thing, according to the temperature in which the process is conducted. When heated to 141° it burns rapidly, and the product is phosphoric acid: when allowed to burn gradually, at the common temperature of the air, the product is phosphorous acid, which contains a smaller proportion of oxygen. The difference between these two acids had been remarked by Sage, by Proust, and by Morveau; but it was Lavoisier who first, in 1777, demonstrated that they form different compounds with other bodies, and that the difference between them is owing to the different proportions of oxygen which they contain.

1. Phosphorous acid is prepared by exposing phosphorus during some weeks to the ordinary temperature of the atmosphere. Even in winter the phosphorus undergoes a slow combustion, and is gradually changed into a liquid acid. For this purpose, it is usual to put small pieces of phosphorus on the inclined side of a glass funnel, through which the liquor which is formed drops into the bottle placed to receive it. From one ounce of phosphorus about three ounces of acid liquid may be thus prepared.

2. Phosphorous acid, thus prepared, is a viscid liquid, of different degrees of consistence, adhering like oil to the sides of the glass vessel in which it is contained. It emits the smell of garlic, especially when heated. Its taste is acid, like that of phosphoric acid, and it produces the same effect upon vegetable colours. Its specific gravity has not been determined.

3. It combines with water in every proportion; but it cannot, like phosphoric acid, be obtained in a concrete state.

When heated, part of the water which it contains is at first evaporated. When large bubbles of air rise to the surface, there they break, and emit a dense white smoke, or even take fire if the experiment is performed in an open vessel. The emission of these bubbles of phosphureted hydrogen gas continues for a long time. When the process is finished, the acid which remains is no longer phosphorous, but phosphoric acid. These phenomena would lead one to suspect that phosphorous acid is not, as has been hitherto supposed, a compound of phosphorus and oxygen; but that it is phosphoric acid saturated with phosphureted hydrogen gas.

4. This acid is converted into phosphoric acid by exposure to air or oxygen gas. The process is exceedingly slow, and the conversion is never complete. It succeeds better when the acid is diluted with a great proportion of water.

5. Phosphorous acid is not acted upon by any of the simple combustibles except charcoal, and perhaps also hydrogen. Charcoal decomposes it at a red heat as well as phosphoric acid. The products are carbonic acid and phosphorus. It does not act on the simple incombustibles.

6. Its action on metals is exactly similar to that of phosphoric acid, excepting only that the hydrogen gas evolved during the oxydisement of the metals has a fetid smell, and holds phosphorus in solution.

7. It combines with alkalies, earths, and metallic oxides, and forms compounds distinguished by the name of phosphites.

8. Sulphuric acid produces no change upon it while cold; but at a boiling heat it parts with some of its oxygen, and the phosphorous acid is converted into phosphoric. Nitric acid also, when assisted by heat, converts it readily into phosphoric acid. This furnishes us with by far the best process for obtaining phosphoric acid at present known.

9. The affinities of phosphorous acid, as ascertained by Bergman, Fourcroy, and Vauquelin, observe the following order:

Lime,
Barytes,
Strontian,
Potass,
Soda,
Ammonia,
Glucina,
Alumina,
Zirconia.

This acid has not hitherto been put to any use. The history of its preparation is sufficient to convince us, that it is composed of the same constituents as phosphoric acid: but the exact proportion of these constituents has not hitherto been ascertained.

PHOSPHORUS, in chemistry, a combustible substance remarkable for its strong attraction for oxygen, and which consequently spontaneously inflames in the open air at a moderate temperature.

History of its discovery. It was accidentally discovered by Brandt, a chemist of Hamburgh, in the year 1669, as he was attempting to extract from human urine a liquid capable of converting silver into gold. He showed a specimen of it to Kunkel, a German chemist of considerable eminence, who mentioned the fact as a piece of news to one Kraft, a friend of his at Dresden. Kraft immediately repaired to Hamburgh, and purchased the secret from Brandt for 200 dollars, exacting from him at the same time a promise not to reveal it to any other person. Soon after he exhibited his phosphorus publicly in Britain and France, expecting doubtless that it would make his fortune. Kunkel, who had mentioned to Kraft his intention of getting possession of the process, being vexed at the treacherous conduct of his friend, attempted to discover it himself; and about the year 1674 he succeeded, though he only knew from Brandt that urine was the substance from which phosphorus had been procured. Accordingly he is always reckoned, and deservedly too, as one of the discoverers of phosphorus.

Boyle likewise discovered phosphorus, and revealed the process to Godfrey Hankwitz, a London apothecary, who continued for many years to supply all Europe with phosphorus. Hence it was known to chemists by the name of English phosphorus.

Phosphorus may be procured by the following process: Let a quantity of bones be burnt, or, as it is termed in chemistry, calcined, till they cease to smoke, or to give out any odour, and let them afterwards be reduced to a fine powder. Put 100 parts of this powder into a bason of porcelain or stone ware, dilute it with four times its weight of water, and then add gradually (stirring the mixture after every addition) 40 parts of sulphuric acid. The mixture becomes hot, and a vast number of air-bubbles are extricated. Leave the mixture in this state for 24 hours; taking care to stir it well every now and then with a glass or porcelain rod, to enable the acid to act upon the powder.

The whole is now to be poured on a filtre of cloth; the liquid which runs through the filtre is to be received in a porcelain bason; and the white powder which remains on the filtre, after pure water has been poured on it repeatedly, and allowed to strain into the porcelain bason below, being of no use, may be thrown away.

Into the liquid contained in the porcelain bason, which has a very acid taste, sugar of lead, dissolved in water, is to be poured slowly; a white powder immediately falls to the bottom: the sugar of lead must be added as long as any of this powder continues to be formed. Throw the whole upon a filtre. The white powder which remains upon the filtre is to be well washed, allowed to dry, and then mixed with about one-sixth of its weight of charcoal-powder. This mixture is to be put into an earthenware retort. The retort is to be put into a sand-bath, and the beak of it plunged into a vessel of water, so as to be just under the surface. Heat is now to be applied gradually till the retort is made red-hot. A vast number of air-bubbles issue from the beak of the retort, some of which take fire when they come to the surface of the water. At last there drops out a substance which has the appearance of melted wax, and which congeals under the water. This substance is phosphorus.

Properties. 1. Phosphorus, when pure, is semitransparent, and of a yellowish colour; but when kept some time in water, it becomes opaque externally, and then has a great resemblance to white wax. Its consistence is nearly that of wax; it may be cut with a knife, or twisted to pieces with the fingers (a dangerous process). It is insoluble in water. Its mean specific gravity is 1.77.

2. It melts at the temperature of 99°. Care must be taken to keep phosphorus under water when melted; for it is so combustible, that it cannot easily be melted in the open air without taking fire. When phosphorus is newly prepared, it is always dirty, being mixed with a quantity of charcoal-dust and other impurities. These impurities may be separated by melting it under water, and then squeezing it through a piece of clean shamoy-leather. It may be formed into sticks, by putting it into a glass funnel with a long tube, stopped at the bottom with a cork, and plunging the whole under warm water. The phosphorus melts, and assumes the shape of the tube. When cold, it may be easily pushed out with a bit of wood. If air is excluded, phosphorus evaporates at 219°, and boils at 554°.

3. When phosphorus is exposed to the atmosphere, provided the temperature is not lower than 43°, it emits a white smoke, which has the smell of garlic, and is luminous in the dark. This smoke is more abundant the higher the temperature is, and is occasioned by the gradual combustion of the phosphorus, which at last disappears altogether.

4. When a bit of phosphorus is put into a glass jar filled with oxygen gas, part of the phosphorus is dissolved by the gas at the temperature of 60°; but the phosphorus does not become luminous unless its temperature is raised to 80°. Hence we learn, that phosphorus burns at a lower temperature in common air than in oxygen gas. This slow combustion of phosphorus, at the common temperature of the atmosphere, renders it necessary to keep phosphorus in phials filled with water. The water should be previously boiled to expel a little air, which that liquid usually contains. The phials should be kept in a dark place; for when phosphorus is exposed to the light, it soon becomes of a white colour, which gradually changes to a dark brown. When thus altered, the French chemists give it the name of oxide of phosphorus; supposing it now to be no longer pure phosphorus, but phosphorus combined with a little oxygen. Phosphorus, when newly prepared, always contains some of this oxide of phosphorus mixed with it; but it may be easily separated by plunging the mass into water heated to about 100°. The phosphorus melts, while the oxide remains unchanged, and swims upon the surface of the melted phosphorus.

5. When heated to 148°, phosphorus takes fire and burns with a very bright flame, and gives out a great quantity of white smoke, which is luminous in the dark; at the same time it emits an odour which has some resemblance to that of garlic. It leaves no residuum; but the white smoke, when collected, is found to be an acid.

On examining the acid produced during the combustion of phosphorus, it is found that it is a peculiar acid, now known by the name of phosphoric acid, which see.

The combustion of phosphorus, like that of sulphur, is nothing else than its combination with oxygen: for during the process no new substance appears, except the acid, accompanied indeed with much heat and light.

6. Phosphorus combines readily with sulphur, and the two substances are capable of being mixed in different proportions. Seventy-two grains of phosphorus and nine of sulphur, when heated in about four ounces of water, melt with a gentle heat. The compound remains fluid till it is cooled down to 77°, and then becomes solid. These substances were combined in the same manner in the following proportions:

4 Phosphorus, 1 Sulphur	congeals at 59°
4 Phosphorus, 2 Sulphur	- - at 50°
4 Phosphorus, 4 Sulphur	- - at 41°
4 Phosphorus, 12 Sulphur	- - at 99°.

When the phosphorus predominates, this compound is called phosphuret of sulphur; when the sulphur exceeds, it is called sulphuret of phosphorus.

Phosphorus and sulphur may be combined also by melting them together without any water; but the combination takes place so rapidly, that they are apt to rush out of the vessel if the heat is not exceedingly moderate.

7. Phosphorus is capable likewise of combining with many other bodies; the compounds produced are called phosphurets, which see.

8. Phosphorus, when used internally, is poisonous. In very small quantities (as one-fourth of a grain), yet when very minutely divided, it is said by Leroi to be very efficacious in restoring and establishing the force of young persons exhausted by sensual indulgence.

The affinities of phosphorus have not yet been ascertained.

PHOSPHURETS, substances formed by an union of the alkalies, earths, and metallic oxides, with phosphorus. Thus we have phosphuret of lime, &c.

PHOSPHURET *of Antimony.* When equal parts of antimony and phosphoric glass are mixed together with a little charcoal-powder, and melted in a crucible, phosphuret of antimony is produced.

PHOSPHURET *of Barytes* may be formed by putting a mixture of phosphorus and barytes into a glass tube close at one end, and heating the mixture by putting the tube upon burning coals. These instances will be sufficient to explain the nature of phosphurets in general.

PHOTINIANS, a sect of Christians in the fourth century, so called from Photinus, their chief, who was bishop of Sirmich, and maintained that Jesus Christ was true man, but not true God, nor born before all ages; and that he only began to be Christ when the Holy Spirit descended upon him in the river Jordan.

PHOTOMETER, *Measurer of Light*, in a cloudy or bright day, or between different luminous bodies. A good instrument of this kind is still a desideratum in philosophy.

PHRASE, in grammar, a manner of speech peculiarly adapted to certain occasions, arts, languages, &c.

PHRENETIC VESSELS. See ANATOMY.

PHRENSY. See MEDICINE.

PHRYGANEA, a genus of insects of the order neuroptera. The generic character is, mouth without teeth, with four feelers; stemmata three; antennæ longer than thorax; wings incumbent, the lower pair pleated.

The genus phryganea consists of insects which in point of habit or general appearance bear a considerable resemblance to some of the phalænæ, and particularly to those belonging to the division entitled tineæ. They may however be readily distinguished from moths by their palpi or feelers, as well as by the stemmata situated on the top of the head. The phryganeæ proceed from aquatic larvæ of a lengthened shape, residing in tubular cases, which they form by agglutinating various fragments of vegetable substances, particles of gravel, &c. &c. These tubular cases are lined within by a tissue of silken fibres, and are open at each extremity. The included larvæ, when feeding, protrude the head and fore parts of the body, creeping along the bottom of the waters they inhabit, by means of six short and slender legs: on the upper part of the back, in most species, is situated an upright papilla or process.

serving as a kind of prop or stay, preventing the case or tube from slipping too forwards during the time the animal is feeding.

Of the European phryganeæ, one of the largest is the phryganea grandis of Linnæus, usually measuring somewhat more than an inch in length, and having very much the general aspect of a phalæna: the upper wings are grey, marked by various darker and lighter streaks and specks, and the under wings yellowish-brown and semitransparent. The larva, which measures near an inch and three quarters in length, is of a flesh-coloured grey, with brown head and legs, and inhabits a tube composed of pieces of bark, small fragments of grass-stalks, or other substances. Like other larvæ of this genus, it is known by the name of cadew-worm, or cad-bait, and is frequently used by anglers as a bait. When arrived at full growth, it fastens the case or tube by several silken filaments to the stem of some water-plant, or other convenient substance, in such a manner as to project a little above the surface of the water; and casting its skin, changes to a chrysalis of a lengthened shape, and displaying the immature limbs of the future phryganea, which in the space of about fourteen days emerges from its confinement.

Phrygania rhombica is a smaller species than the former, and is of a yellowish-brown colour, with two obliquely transverse rhomboid semitransparent white spots on each upper wing; the lower wings being whitish, with a tinge of yellow-brown towards the upper edge. The larva forms its case of small pieces of the slender stems of water-grasses or other plants, curiously disposed in an obliquely transverse direction. It is of a greenish-brown colour, and like the former, is found in rivulets and stagnant waters. The larvæ of the phryganeæ in general feed not only on the smaller water-insects, but on the spawn of fishes, and even on the young fry itself. There are twenty-four species.

PHRYMA, a genus of the didynamia gymnospermia class and order. The essential character is, seed one. There are two species, herbs of North America and the Cape.

PHRYNIUM, a genus of the monandria monogynia class and order. The calyx is three-leaved; petals three, equal; nectarine; tube filiform; border four-parted; capsule three-celled; nuts three. There is one species, a plant of Malabar.

PHTHISIS. See MEDICINE.

PHYGETHLON, in surgery, a broad, but not much elevated tumour, of the same nature with the bubo. See the article BUBO.

PHYLACTERY, in antiquity, a charm or amulet, which being worn, was supposed to preserve people from certain evils, diseases, and dangers. The Jews were remarkable for wearing phylacteries of parchment, in the form of slips or rolls, wherein were written certain passages of the law: these they wore upon their foreheads, and upon the wrists of their left arms. The modern Jews think themselves under no obligation to this practice, which they observe only at morning prayers.

PHYLACHNE, a genus of the diœcia monandria class and order. The calyx is three-leaved, superior; corolla funnel-form; fem. stigma four-cornered; capsule inferior, many-seeded. There is one species, a small mossy plant of South America.

PHYLICA, *bastard alaternus*, a genus of the monogynia order, in the pentandria class of plants; the perianthium five-parted, turbinate; petals none; capsule tricoccous. There are twenty species, of which three are commonly kept in the gardens of this country; but being natives of warm climates, they require to be kept in pots, and housed in winter. They are all shrubby plants, rising from three to five or six feet high, and adorned with beautiful clusters of white flowers. They are propagated by cuttings.

PHYLLANTHUS, *sea-side laurel*; a genus of the triandria order, in the monœcia class of plants. The male calyx is six-parted, bell-shaped; no corolla; female calyx six-parted; styles three, bifid; capsules three-celled; seeds solitary, roundish. There are eleven species, all of them natives of warm climates; and rise from twelve or fourteen feet to the height of middling trees. They are tender, and cannot be propagated in this country without artificial heat.

PHYLLIS, a genus of the pentandria digynia class and order. The stigmas are bispid, fructifications scattered; cal. two-leaved, obsolete; corolla five-petalled; seeds two. There is one species, a herb of the Canaries.

PHYSALIS, the *winter cherry*, a genus of the monogynia order, in the pentandria class of plants. The corolla is wheel-shaped; stamina converging; berry within an inflated calyx, two-celled. There are seventeen species, of which the most remarkable is the alkekengi, or common winter-cherry. This grows naturally in Spain and Italy. The flowers are produced from the wings, standing upon slender footstalks; they are of a white colour, and have but one petal. They are succeeded by round berries about the size of small cherries, inclosed in an inflated bladder, which turns red in autumn; when the top opens and discloses the red berry, which is soft, pulpy, and filled with flat kidney-shaped seeds. The plant is easily propagated, either by seeds, or parting the roots; and is very hardy.

PHYSETER, CACHALOT, a genus of fishes of the order cete. The generic character is, teeth visible in the lower jaw only; spiracle on the head or snout. 1. Physeter macrocephalus, blunt-headed cachalot. This whale, which is one of the largest species, is scarcely inferior in size to the great mysticete, often measuring sixty feet or more in length. The head is of enormous size, constituting more than a third of the whole animal; the mouth wide; the upper lip rounded, thick or high, and much broader than the lower; which is of a somewhat sharpish form, fitting, in a manner, into a longitudinal bed or groove in the upper. The teeth, at least the visible ones, as mentioned in the generic character, are situated only in the lower jaw; and when the mouth is closed, are received into so many corresponding holes or cavities in the upper: they are pretty numerous, rather blunt, and of a somewhat conic form, with a very slight bend or inclination inwards. There are also, according to Fabricius, small, curved, flattish, concave, and sharp-pointed teeth, lying almost horizontally along the upper jaw; though, from their peculiar situation and size, they are not visible like those of the lower; being imbedded in the fleshy interstices of the holes which receive the lower teeth, and presenting only their internal concave surfaces to meet the latter when the mouth is closed. The front of the head is very abrupt, descending perpendicularly downwards; and on its top, which has been improperly termed the neck by some authors, is an elevation or angular prominence containing the spiracle, which appears externally simple, but is double within. The head is distinguished or separated from the body by a transverse furrow or wrinkle. The eyes are small and black; and the ears or auditory passages extremely small. About the middle of the back is a kind of spurious fin, or dorsal tubercle, of a callous nature, not moveable, and somewhat abrupt or cut off behind. The tongue is of the shape of the lower jaw, clay-coloured externally, and of a dull red within. The throat is but small in proportion to the animal. The body is cylindrical beyond the pectoral fins, growing narrower towards the tail. The colour of the whole animal is black, but when advanced in age grows whitish beneath. It swims swiftly, and is said to be a violent enemy to the squalus carcharias, or white shark, which is sometimes driven ashore in its endeavours to escape, and according to Fabricius, will not venture to approach its enemy, even when dead, though fond of preying on other dead whales. This whale also devours the cyclopterus lumpus, or lump-fish, and many others. The Greenlanders use the flesh, skin, oil, tendons, &c. in the same manner as those of the narwhal. It is reckoned very difficult to take, being very tenacious of life, and surviving for several days the wounds it receives from its pursuers.

It is in a vast cavity within the upper part of the head of this whale, that the substance called spermaceti is found, which, while fresh and in its natural receptacle, is nearly fluid; but when exposed to the air, concretes into opake masses: this substance being so universally known, it becomes unnecessary to describe it farther.

A more curious and valuable production, the origin of which had long eluded the investigation of naturalists, is obtained from this animal, viz. the celebrated perfume called ambergris, which is found in large masses in the intestines, being in reality no other than the fæces.

2. Physeter catodon, small cachalot. This species is of far inferior size to the former, measuring about twenty-five feet in length. In its general structure, it is allied to the preceding, but has a smaller mouth in proportion, and is without any visible protuberance on the back. It is found in the northern seas.

3. Physeter microps, small-eyed cachalot. This is of equal, and sometimes even superior size to the first-described species, and is a native of the northern seas. The head is very large, and nearly half the length of the body: the eyes extremely small, and the snout slightly obtuse: on the back is a long and somewhat upright narrow and pointed fin. This species swims swiftly, and is said to be a great enemy to the porpoise, which it pursues and preys upon. Its colour is blackish above, and whitish beneath. Some of the supposed varieties of this whale are said to grow to the length of eighty or a hundred feet. The teeth are of a more curved form than the rest of the genus.

Physeter tursio, high-finned cachalot. This is particularly distinguished by the great length and narrow form of its dorsal fin, which is placed almost upright on the back, and is said by some authors to appear at a distance like the mast of a small ship; the animal growing, if we may believe report, to the length of a hundred feet. In its general appearance it is said much to resemble the former species, of which it may perhaps be a variety rather than truly distinct; but so much obscurity still prevails with respect to the cetaceous animals, that this point must be considered as very doubtful.

PHYSICIANS. No person within London, nor within seven miles of the same, shall exercise as a physician or surgeon, except he is examined and approved by the bishop of London, or by the dean of St. Paul's, calling to them four doctors of physic, and for surgery, other expert persons in that faculty, of them that have been approved; upon the pain of forfeiture for every month 5*l.* one half to the king, and the other half to any that will sue. 3 H. VIII. c. 11.

One that has taken his degree of doctor of physic in either of the universities, may not practise in London, and within seven miles of the same, without licence from the college of physicians. And it has been held, that if a person, not duly authorized to be a physician or surgeon, undertakes a cure, and the patient dies under his hands, he is guilty of felony; but he is not excluded from the benefit of clergy.

PHYSICS, called also physiology, and natural philosophy, is the doctrine of natural bodies, their phenomena, causes, and effects, with their various affections, motions, operations, &c. So that the immediate and proper objects of physics, are body, space, and motion.

PHYSIOLOGY is a word which, in its etymological signification, comprehends the science of nature in general; modern use, however, has restricted it to that department of physical knowledge which has alone relation to organic existence; and, indeed, when employed as a generic term, without any specific indication, it is made exclusively to denote the science of animal life. Naturally organized bodies are those which have "an origin by generation, a growth by nutrition, and a termination by death." In endeavouring, however, to mark the precise distinction between living or organic, and matter which is inanimate or destitute of vitality, it will be found of considerable import to ascertain the prime characteristic of either, or that to which all other laws influencing them act in subordination.

It is indivisibility, or mutual connection of parts with the whole, which appears to constitute the essential character of a living organized body. "The mode of existence in each part of inanimate matter belongs to itself, but in living bodies it resides in the whole." Separate a single branch from a tree in the full vigour of vegetation, and the part thus separated shall immediately droop, and shall shortly die; that is, it will cease to be influenced as formerly by air, heat, and other powers which support vegetation; will no longer display those phenomena which had previously resulted from the agency of such powers; will become, in the language of the Brunonian philosophy, unexcitable, and subject to the government of new laws. In the animal creation, also, the same effect will result from the same process: if a limb is separated from an animal body, the life of such limb, without any apparent injury to its organization, will be inevitably destroyed. Supposing we have thus reduced organic to inorganic, living to dead matter, in an animal body, for instance, let us pursue our experiments on the material thus changed; let the part to which we have given a new mode of existence be itself divided, and we shall now find nothing of the like result, as in the first process, to take place; its quality by this last operation will only be altered inasmuch as its quantity is diminished. Each part will be found to have a separate and independant existence. There has been no connecting integral principle interfered with; and, placed exactly under the same external circumstances, an identity in the mode of existence would be retained to the end of time by each division. Let us pursue our experiments still further. Let us subject the two parts to a difference of external circumstance; enclose one in an atmosphere of 40° of heat, the other in 100°, and the consequence will be a deprivation of that identity which till now they had retained. Each part will not continue the same mass of dead matter, but will assume a new character. Now it will be evident that in these experiments we have operated an essential change; and in each, of an essentially different nature. By seperating a part from the whole of an organic body, we effect the loss of its vitality, even though such external agents shall continue to be applied as previously operated its life and growth. By a further mechanical separation we do not effect an alteration in quality, in any other way than as this will depend on quantity, until we occasion a change in exterior agents; by which change, however, we finally ensure an actual alteration of principle or composition, as well as of aggregate power.

We have thus endeavoured to illustrate the simple and prime characteristic of organic as separated from inorganic being. But physiology we have said, according to the general acceptation of the word, confines its researches to animal life; what this last has peculiar to itself, it will be proper further to state. The usual division of organized existence is into animal and vegetable; the former possessing those faculties from which result sensation and loco-motion; the latter being destitute of such faculties: an opinion indeed has recently been hazarded that such division is unfounded and artificial; that vegetable and animal life are subject to the same laws; that plants are not merely organized, but animalized; that their motions indicate sensation and consequent volition. To enquire into the grounds of these assumptions, does not fall within the province of the present article; we are to take for granted the negative of the proposition, and proceed to consider first, the primary faculties, and secondly, the resulting functions, of those existences which are universally acknowledged to be possessed of the powers of feeling and of motion, and are truly and evidently animalized.

Of Sensibility, Irritability, and the Vital Principle.

Sensibility has been defined, the faculty which organs have of feeling; the aptitude they possess of perceiving, by the contact of an extraneous body, an impression more or less powerful, which changes the order of their motions, accelerates or retards, suppresses or completes them. "This faculty," says the author from whom we have taken the definition (M. Richerand), "generally diffused in our organs, does not exist in all to the same degree. In some it is obscure and scarcely apparent, and seems reduced to a degree absolutely indispensable for the fluids to determine the actions necessary to the functions they ought to perform. It should seem that no part of the body can do without this sensibility absolutely necessary for life. Without it, how could various organs act upon the blood, to draw from it the means of their nutrition, or materials for the different secretions? Therefore this degree of sensibility is common to every thing which has life; to animals and vegetables; to a man when asleep and awake; to the fœtus, and the infant; to the organs of assimilating functions; and to those which put us on a level with surrounding beings. This low degree of sensation could not have been sufficient for the existence of man, and of beings resembling him, exposed to numerous connections with every thing that surrounds them; therefore they possess a sensibility far superior, by which the impressions affecting certain organs are perceived, judged, compared, &c. This sort of sensibility would be more properly called perceptibility, or the faculty of judging of the motions experienced. It requires a centre to which the impressions have a mutual relation; therefore it only exists in animals which, like man, have a brain, or something equivalent in its place; whilst zoophytes and vegetables, not possessing this central organ, are both destitute of this faculty; however, polypi, and several plants, as the sensitive, have certain spontaneous motions, which seem to indicate the existence of volition, and consequently of perceptibility; but these actions, like that of a muscle from the thigh of a frog excited by the galvanic stimulus, are occasioned by an impression that does not extend beyond the part itself, and in which sensibility and contractility exist in a confused state." Elements of Physiology by A. Richerand, translated edition.

By the above definition and description of simple sensibility, as opposed to perceptibility, it will appear that our author does not consider sensation as the necessary consequence of the faculty which he terms sensibility.

The author, however, whom we have quoted, admits that this kind of latent and imperceptible sensibility "cannot be exactly compared to that of vegetables, since the parts in which it resides, generally possessing such a small share of sensibility in a state of health, have an increased or percipient degree of sensibility when in a state of disease;" and after giving examples of this, he adds, "should it not be suspected that if we have not a consciousness of impressions made upon our organs by the fluids contained in them during health, it is from our being accustomed to the sensations they excite almost uninterruptedly, of which we have only a confused perception, that terminates imperceptibly? And may we not be permitted in this point of view to compare these organs to those in which reside the senses of vision, hearing, smell, taste, and feeling, which can no longer be excited by habitual stimuli to which they have been long accustomed?" We find, however, some difficulty in admitting this principle even with the modification proposed. If sensibility becomes in this manner latent, or we cease to take cognizance of such functions as are exercised independantly of the will merely by the force of habit, does it not follow that the origin of these functions, at least in their aggregate, would have been accompanied by more sensation than is consistent with the healthy state? Thus the moment an animal became conscious of existence, it would be the subject of impression sufficiently violent to destroy, or at least to derange life. Does it not appear that involuntary living action results from a principle dissimilar to that which is preceded by sensation; and that the sensibility here spoken of is a kind of intermediate faculty between that which gives sensation and volition, and that upon which muscular irritation or contraction from stimuli depends? When the galvanic experimenter excites actions in the muscles on the insulated thigh of a frog, it cannot be supposed that such actions are attended by perception (for, as it has been properly observed by M. Cuvier, "it appears repugnant to the notions we entertain of self, and of the unity of our being, to admit the possession of sensation by these fragments"); although the actions are excited through the medium of nervous excitability, and are of a different nature from those which would follow a mere irritation of the muscular fibre. May we not then conclude that the nervous organization is endowed with a susceptibility independantly of actual, or what M. Richerand perhaps improperly denominates percipient, sensibility; and that it is through the medium of this faculty that the incessant and unperceived performance of the vital functions is accomplished? When the voluntary faculty ceases to acknowledge its accustomed and appropriate stimuli; when sensation for a time is totally suspended, as in apoplexy, or in experiments on frogs by pouring opium on the brain of these animals; the functions of vitality are still preserved by means of the susceptibility now alluded to. We have elsewhere endeavoured to prove that convulsive agitation, whether taking place in the muscles of volition, or in those organs which are independant of the will, results from deficient or transient excitement (see MEDICINE, section *Nervous Diseases*); and such defective excitement seems to result from an unhealthy condition of this nervous susceptibility, which, in instances of sudden death produced by an abrupt and entire abolition of the sentient and loco-motive faculty, for some time longer lingers in the system, deranged indeed, but not yet destroyed, and produces those spasmodic motions which are observed in an animal body under the circumstances which we are now supposing. When, for instance, a domestic fowl is deprived of life, either by its head being severed from its body, or by the more common mode of screwing the neck, a spasmodic convulsive kind of vellications will be observed, and indicate the remains of this susceptibility of action, for some time after perception or actual sensation is gone. If the principle now contended for is admitted, our compassion for the animal in this state would be misapplied; and it must likewise follow that the notion which has been maintained by some is altogether erroneous, of death from decapitation being a lingering, and therefore cruel, mode of terminating existence. In the case, however, of articulated worms, a like separation of parts does not appear to operate the same immediate destruction of the sensitive and loco-motive faculty; for as in them there is no single brain, but ganglia, as the centres of sensation and commencing points of volition. Each part of a divided worm is thus a distinct living and sentient being. From the remains of this principle of susceptibility may originate those convulsive affections which almost invariably precede death in the course of nature, and which are oftentimes exhibited in a violent degree for some time posterior to the departure of the sentient or perceiving faculty; but which last is itself destroyed prior to the total destruction of muscular irritability, or the vis insita of Haller. This last (Hallerian irritability) is denominated by modern physiologists, contractility. As actual sensation is demonstrably produced through the medium of nerve, so "the general organ of motion is the fleshy or muscular fibre. This fibre contracts itself by volition, but the will only exercises this power through the medium of the nerves. Every fleshy fibre receives a nervous filament, and the obedience of the fibre ceases when the communication of that filament with the rest of the system is interrupted. Certain external agents applied immediately to the fibre likewise cause contractions, and they preserve their action upon it even after the section of its nerve, or its total separation from the body, during a period which is longer or shorter in different species of animals. This faculty of the fibre is called its irritability. Does it in the latter case depend upon the portion of the nerve remaining in the fibre after its section, which always forms an essential part of it? or is the influence of the will only a particular circumstance, and the effect of an irritating action of the nerve on a faculty inherent in the muscular fibre? Haller and his followers have adopted the latter opinion; but every day seems to add to the probability of the opposite theory."—Cuvier's Comparative Anatomy.

If, however, we resort to analogy, which, in the present state of our knowledge with respect to the composition of muscular fibre, is all the aid with which we are furnished to solve the question of distinct or separate residences of nervous and muscular power, we should perhaps be compelled to revert to something like the Hallerian doctrine of a vis insita, or independant excitability, and conclude that the nerves are merely instruments by which the faculty of contractility is developed, and that this faculty may otherwise be produced by extraneous stimuli, without the interference of the nerves. Many plants are possessed of contractile, although not (as it appears) of actually sensitive and loco-motive power: this contractility, from the mode of its excitation, and from the phenomena which it exhibits, seems in every way similar to the irritability of the animal fibre, nevertheless neither brain nor nerves have hitherto been detected in vegetables. The attempts to prove that irritability and sensibility are one, seem to proceed from the general tendency observed in the philosophy of the present period, to strain the analogy between vegetable and animal life. M. Delametherie, a French physiologist, carries this doctrine to the extent of denying the existence in toto of any distinct muscular fibre. The substance which has been ordinarily considered to be muscle, he considers as "a congeries of blood-vessels, lymphatics, and nervous filaments, bound together by cellular membrane, in the interstices of which are deposited animal gelatine and fat." Considerations sur les Etres organisés, &c.

It appears to us, however, that sensibility and irritability, although intimately connected, and never separate in a living animal body, are yet distinct principles; at least, that more and stronger facts than have hitherto been advanced, are requisite to the full establishment of the modern doctrine, "that they are in effect the same property."

Irritability, or the power of contraction upon the application of stimuli, has been divided into two species; the one has been named by some physiologists the tonic power, the other musculosity: this difference, however, rather refers to the difference of exciting power, by which is called into action the one and the other; "the slow, gradual, and tonic-like action of the bladder in expelling the urine," seems principally to vary from that of the voluntary muscles by being more beyond the influence and caprices of the will.

The most remarkable characteristic both of sensibility and irritability (forming together vital excitability) is, that as they are subservient to different purposes, and resident in various organs, they are susceptible of developement or excitation, by peculiar and respective agents. Thus light is a stimulus to the eye, sound to the ear, a sapid substance to the taste, and an odoriferous body the smell. Thus mercury will stimulate the hepatic, foxglove the renal viscus, although in each instance the indivisible faculties of sensibility or irritability are called into play; and no difference indicating peculiar excitability can be traced by the anatomist in the arrangement, or the chemist in the composition, of the ultimate fibrillæ constituting either the nerves or the contractile organs of these respective parts.

The animal frame is thus supported in the same manner as a piece of complicated machinery, composed of several springs, each of which is kept in exercise by a principle peculiar to itself, while the combined effect of them all is one resulting whole, effected by one prime and operating principle; this, in the living machine, is named the vital principle, of which we are now to speak.

Researches into the nature and cause of living actions, appear to have been impeded by errors arising from different, and in one sense, opposite sources; the one of old, the other of modern date. The earliest philosophers could not have been long in observing, while contemplating the phenomena of life, "that it exhibits an order of truths peculiar to itself, which is no where to be found beyond the sphere of living existence." (Dumas.) Before the proper boundaries were discovered of human research, and the true nature of philosophizing ascertained, these phenomena were accounted for by the supposition of an occult agency endowed with intelligence, and acting with design; hence the origin of the vague terms archæus, or presiding power, vis naturæ medicatrix, nature, and other expressions, the inventors of which do not appear to have been conscious that they not merely amount to a confession of ignorance, but mislead the judgment by attaching it to certain preconceived systems framed from ideal knowledge. It is the province of philosophy not to imagine but to infer. When it is observed, that life in all its modifications and stages, requires for its developement and maintenance the incessant agency of peculiar powers on matter peculiarly constructed, as in the experiments before alluded to, we are not merely justified in concluding, but we are irresistibly impelled to the inference, that the combination of effects to which we have applied the term life results from such agency on such organized matter. The nature of the link which constitutes this connection may for ever be concealed, but the connection itself is demonstrated. The idea of life then is not to be confounded either with the abstract nature of the matter acted upon, or the agents through the medium of which it is produced. "There is no interior independant spring of action or support," there is no exterior abstract power. In the employment then of the term vital principle, we ought to be regarded as simply announcing a fact, not as conveying a notion of cause; and in this view it will appear, contrary even to the sentiments of some authors from whom it is almost temerity to differ, that the passive rather than the active voice of verbs, should be made use of in calculations on vital forces and effects. See the articles BRUNONIAN SYSTEM; and likewise MEDICINE, section *Fever*.

But an error from a different source than that just alluded to, appears to have insinuated itself into the physiology of the present day, viz. that of too hastily registering under one head, facts which both in their origin and result, are of a nature essentially different. We allude to the chemico-animal philosophy which has recently become so prevalent, especially in the French and German schools. Against this physiology we do not think it right to urge the objection which has been advanced, that it encourages materialism, and leads to conclusions destructive of morality; for besides that we doubt the justness of the accusation, it ought always to be recollected, that it is not until physiology terminates, that metaphysic commences.

In consequence of the radical change which has recently been effected in the whole body of chemical science, physiological researches have received a fresh impulse and a new direction. By modern chemistry many facts in the animal economy have been fully developed, which were before concealed. Such, however, is the proneness of mankind to extremes, that in this as in other instances, the auxiliary has been made to usurp the rights of the principal; chemical affinity has been supposed fully explicative of living actions, and the idea of animation being regulated by a distinct principle ridiculed as visionary. We believe, however, the ridicule to have been misapplied; and though equally ready with our modern physiologists to oppose the admission of "an occult cause" as the cause of life, we must still maintain that the attractions of matter, in the mode they contend for, are of a nature very different from those resulting from the agency of the life-producing powers on an organized body. For example: muscular contraction is generated by an abundant variety of external stimuli; among these, oxygen has been found to be one of the most active; the effect of the above agent has been therefore preposterously confounded with the agent itself, oxygen has been imagined to be the principle of irritability, and the developement of life by consequence has been supposed immediately to result from its combination with the animal fibre: with equal justice might opium or any other stimulus be in this manner as it were vitalized.

But it will be urged that the oxygenous theory of life has been abandoned; nor should we perhaps be justified in bringing it to notice, did it not appear that those hypotheses which are at this instant in repute are founded upon precisely the same principles with the conjectures which originated with Dr. Girtanner. Thus it has been inferred that the newly discovered source of nervous excitation operates upon the muscles, by virtue of an attractive power in the muscular fibre for the galvanic fluid, much in the same manner as an acid rushes into combination with an alkali, or as oxygen unites itself with an inflammable base. "I suppose, (says M. Delametherie) that muscular contraction is produced by the heat which accompanies the extrication of the galvanic fluid, upon the same principle that a piece of skin contracts which is brought near the fire, or on which is poured a concentrated acid, a caustic alkali, or any other caustic body."

From such mode of reasoning it has been inferred, that the science of medicine is resolvable into a combination and separation of principles as in the chemist's laboratory; and that life and health are to be preserved and restored in the same manner as a fluid body is made viscid by the introduction of a foreign principle. Thus we have found in the writings of medical systematics of this class the processes described, and the results confidently anticipated, of oxygenating, deoxygenating, hyperoxygenating, and galvanizing, the animal frame.

It is however obvious, that these speculations are fundamentally erroneous; for life and health are built upon a firmer basis than that either of aggregative or chemical attraction. The intimate bond of union between every the most minute portion of a living body, must be severed, the indivisibility of the frame must first be dissolved, in a word life must have deserted the body, before the above powers can be admitted. In what manner, according to the tenets we are now canvasing, could that remarkable property of animal life (caloricité) be preserved, of retaining a regular quantity of interior, amidst all the vicissitudes of exterior, heat? Almost every chemical combination is effected by a variation, and in very many cases, a trivial variation, in temperature; but the living body is capable of sustaining or of resisting heat to a degree which would immediately change animal or vegetable substance deprived of life into substance of a totally different nature.

Life, in the systems we are commenting upon, appears, as before observed, to be confounded with that which produces or elicits life. Vital phenomena are not observed and arranged in their natural and regular sequence; enquiries are instituted from a wrong point; thus, although we even accede to the position of M. Cuvier, "that the living and contracted muscular fibre is not, strictly speaking, the same body, nor composed of the same chemical materials, as the relaxed or inactive fibre," we are not therefore compelled to the alternative of referring the commencement of muscular action to a change of affinity; or with Humboldt and others, to acknowledge that the primary operation of every agent on living matter is virtually an instance of chemical combination.

Let us follow in idea, the influence of the most minute portion of some materials which effect an instantaneous change on every the most distant fibre of the body, we shall often find, for instance, an immediate excitation of all the vital functions, result from their reception into the stomach; now, allowing that the change thus operated occasions an abundance of new combinations strictly chemical, in the fluids and solids, does it therefore follow that the primary impulse on the excitability is a chemical process? if so, how could a similar result be obtained from a cause ab origine mental? or how could the mandates of the will contract the fibre?

Without further enlargement, therefore, (and was it not for the practical importance of the subject, we should conceive an apology already due to the reader,) we trust we may be permitted to conclude, that as the natural philosopher demonstrates a particular quality in bodies to be proportioned to their quantity, and designates this principle by the term gravitation; as the chemist finds the mixture of two different bodies to form a third, and refers it to the affinity of their minute particles; so the physiologist, recognizing the difference of character in the phenomena of life from either of the above modifications of being, makes a separate register or classification of such phenomena, under the comprehensive title of the vital principle; in other words, that "the primary motions of matter (or rather we should say, laws of nature) are capable of division into the three classes of gravitation, chemistry, and life."

In the above sketch we have confined our observations to what may be regarded the great characteristic of living existence, indivisibility; under the immediate influence of which the individual is preserved, and the species propagated; or the secondary faculties are exercised, of assimilation and generation; these faculties we might now proceed to notice; but as they branch out into several functions, it will be more consistent with our limits to refer their consideration to such functions which we are now to describe, together with those resulting from sensibility and irritability, which it was however first necessary to view as in a manner constituent parts of an indivisible whole.

The following table (which we have taken from M. Richerand) presents, perhaps, the most comprehensive and accurate plan which has been formed of vital functions; we shall therefore follow its arrangement, and in instances where these functions have been treated of under separate heads, refer to them under their respective titles.

Plan of a new Classification of the Functions of Life.

- **Class I.** *Functions which serve for the preservation of the individual. (Individual life.)*
  - **Order I.** Functions which assimilate the aliment by which the body is nourished. *(Assimilating, internal, or digestive functions.)*
    - Genus 1. *Digestion* extracts the nutritive part.
      - Reception of the food,
      - Mastication,
      - Solution by the saliva,
      - Deglutition,
      - Digestion in the stomach,
        - duodenum
        - intestines,
      - Excretion of the fæces and urine.
    - Genus 2. *Absorption* carries it into the mass of humours.
      - Inhalation of chyle,
        - lymph,
      - Action of vessels,
        - glands,
        - the thoracic duct,
    - Genus 3. *Circulation* propels it towards the organs.
      - Action of the heart,
        - arteries,
        - capillary vessels,
        - veins.
    - Genus 4. *Respiration* combines it with atmospheric oxygen.
      - Action of the parietes of the thorax,
        - lungs,
      - Alteration of the air,
        - in the blood,
      - Disengagement of animal heat.
    - Genus 5. *Secretion* causes it to pass through several modifications.
      - Exhalation,
      - Secretion by follicles,
        - glands.
    - Genus 6. *Nutrition* applies it to organs, to which it is to supply growth and restore their loss.
      - Different in every part according to the peculiar composition of each.
  - **Order II.** Functions which form connections with surrounding objects. *(External or relative functions.)*
    - Genus 1. *Sensations* inform the being of their presence.
      - Organs of
        - the sight,
        - hearing,
        - smell,
        - taste,
        - feeling.
      - Action of nerves,
        - the brain.
      - Human understanding,
      - Sleep and watching,
      - Dreaming and sleep-walking,
      - Sympathy,
      - Habit.
    - Genus 2. *Motions* approach towards or remove it from them.
      - Organs and muscular motion,
      - The skeleton,
      - Articulations,
      - Place.
      - Progressive motions,
        - Walking,
        - Running,
        - Jumping,
        - Swimming,
        - Flying,
        - Creeping.
    - Genus 3. The *Voice* and *Speech* cause it to communicate with similar beings without change of place.
      - The voice,
        - Articulated, or speech,
        - Modulated, or singing.
      - Stammering,
      - Lisping,
      - Dumbness,
      - Ventriloquism.
- **Class II.** *Functions which serve for the preservation of the species. (Life of the species.)*
  - **Order I.** Functions which require the concurrence of both sexes.
    - *Conception* and *Generation.*
      - General differences of the sexes,
      - Hermaphrodism,
      - Systems relative to generation.
  - **Order II.** Functions which exclusively belong to females.
    - *Gestation.*
      - Of the uterus in a state of impregnation,
      - History of the embryo,
        - fœtus and its membranes,
    - *Delivery.*
      - Of the uterus after delivery,
      - The lochiæ.
    - *Lactation.*
      - Action of the breasts,
      - Milk.
  - **Growth.**
    - Infancy—dentition, ossification,
    - Puberty—menstruation,
    - Adolescence,
    - Youth.

- *Virility.*
  - Temperaments.
    - Sanguine.
    - Muscular,
    - Biliary melancholic,
    - Lymphatic,
    - Nervous.
  - Idiosyncracy.
  - Human race.
    - European,
    - Negro,
    - Mongol,
    - Hyperbolean.
- *Decrease.*
  - Age of decrease.
  - Old age.
  - Decrepitude.
- Death.
- Putrefaction.

Of digestion.

Digestion, or that function by which the dissolution of the aliment is accomplished, and food is thus fitted for the lacteal absorbents, will be found described under the article of Digestion, Vol. I. page 150; and for those varieties in the digestive as of all other organs observed in different animals, the reader is referred to Comparative Anatomy.

Of absorption.

Absorption is that process by which the incessant waste of the system from the various secretions and excretions is constantly repaired. Thus after digestion has converted the aliment into chyle, this fluid is taken up by the lacteals or mesenteric absorbents, undergoes a farther preparation in these vessels, is thence conveyed to the thoracic duct, and at length enters the mass of circulating blood, to furnish the requisite secretions, excretions, and exhalations; in this manner a perpetual change is operated in the materials of which an animal body is composed, "for it should never be forgotten that organized living matter compounds and decompounds itself continually." But this composition and decomposition are perpetually under the influence of fibrous stimulation. "Each orifice of a lacteal and lymphatic, endued with a peculiar degree of sensibility (susceptibility?) and power of contraction, dilates or contracts, absorbs or rejects, according to the mode in which it is affected by substances that are applied to it." Thus when the chyle is applied to the orifices of the lacteal vessels (which have been termed chylous absorbents), it is not solely by means of capillary or any other species of attraction, that this fluid is made to enter its appropriate vessels, but such entrance is gained in virtue of the power possessed by chyle of stimulating these organs; a demonstration of which principle is furnished from those substances being rejected which have not the power of producing that dilatation and contraction just spoken of.

Another curious fact in support of the principle that some substances are not capable of exciting the absorbent vessels, is furnished by those marks which sailors and others are accustomed to imprint on their skin. These are generally formed by first pricking holes in the cuticle, and then rubbing the part over with charcoal or gunpowder, substances which remain undissolved in the fluids, unabsorbed in the lymphatics, and therefore continue through life. Indeed solution is a necessary prelude to every case both of lymphatic and lacteal absorption. It is then by the peculiar action of the lymphatics on exhaled fluids, that lymph is formed; and of the lacteals on the chyle, that this last becomes animalized. Those glandular bodies which are observed in these vessels are supposed to have a very important influence on their contained fluids; and "although it is not known precisely in what these alterations consist of lymph and chyle, it may be said that the object of the glands seems to be, to occasion the most intimate mixture, the most perfect combination of elements; to impress a certain degree of animalization, as proved by the greater concrescibility of lymph taken from the vasa efferentia, or those which pass from glands; to deprive them of mere heterogeneous principles, or, at least, to alter them that they may not become hurtful in passing into the mass of humours." Thus we find, that after absorption has been in the first instance effected by vital action, the contents of the absorbing vessels, still, however, under the same influencing principle, are the subjects of a species of animal chemistry.

As the course of the lymph and the chyle is less rapid than that of the blood, the dilatations, curvatures, and frequent communications of the lymphatics, must considerably obstruct the progress of their contents; but the principal cause of retardation is in the numerous glands just mentioned, which every particle of lymph and chyle has to pass through previously to its entering the blood-vessels.

There are two questions remaining at issue respecting the physiology of the absorbent system: 1st, Whether the distribution of these vessels is universal; and 2d, Whether cutaneous absorption is effected independantly of mechanical violence done to the cuticle. Anatomy has not hitherto detected absorbents in the substance of the brain; but analogy, as well as the circumstances attendant on diseases, disposes us to infer almost with certainty, their existence in every part. The second question, although it has recently been negatived by high authority (Dr. Rousseau, Dr. Currie, M Seguin and others), is generally supposed to be decided in the affirmative. The principal facts in support of the latter opinion are, "the increase of weight in the body after a walk in damp weather, the abundant secretion of the urine after remaining for some time in a bath, the evident swellings of the inguinal glands after long-continued immersion of the feet in water, the effects of mercury administered by friction, the external application of turpentine without friction altering the urine, even when, according to some, its entrance into the system by the lungs had been guarded against, &c." to which Dr. Watson's experiment may be added, of giving a Newmarket jockey, previous to a race, a glass of wine, about an ounce in weight, and finding immediately after the course, he had gained in weight 30 ounces.

Whether actual nutriment is introduced into the system in the way of cutaneous absorption, is perhaps extremely problematical. Dr. Darwin, however, inclines to this opinion, and among the nutrientia in his materia medica, classes both substances that are taken by the surface and likewise by the lungs. Others have supposed, and perhaps with justice, that all matter which is nutritive must be received through the medium of the lacteals.

Of the circulation.

As absorption to digestion, so the description of the blood's circulation naturally follows to absorption, in tracing the mysterious round of animal functions. In describing the circulation, we shall, pursuing the order of the above table, speak first of the action of the heart; secondly, of the arteries and capillary vessels; and thirdly, of the veins.

Of the action of the heart. By referring to the article Anatomy, the reader will find the heart described as consisting of four large cavities, all of which have a communication with each other; of these the two ventricles are in a manner the principal, the auricles the accessary cavities. In following the blood's course through these different divisions, it will be necessary in the first instance to suppose, that each cavity is filled and emptied in a successive order. We then commence the description of the circulation, with the blood returning from every part of the body, and collected in the two venæ cavæ inferior and superior; these joining at their entrance into the right auricle, pour their blood into this auricle, which by consequence immediately contracts, and forces the received blood principally into the contiguous ventricle: a small part, however, flows back into the cavæ. The right ventricle now distended likewise immediately contracts, and the blood is prevented from returning by the tricuspid valve, so that only a small part flows back, while the principal stream passes on into the pulmonary artery, at the entrance of which are the sigmoid valves. The blood is now impelled forwards through all the very minute divisions of the pulmonary artery, and by consequence through the lungs; in these organs it is exposed to the air by the intervention of only a very thin membrane. It now returns essentially altered, through the pulmonary veins, into the left or more properly posterior auricle; this cavity contracts in the same manner with the right or anterior; there is a very partial reflux of blood into the pulmonary veins, while the greater portion is conveyed to the left ventricle, whence it circulates through all the parts of the body; its return into the auricle being prevented by the tricuspid, into the ventricle from the aorta by the semilunar valves.

In the natural course of circulation, the above order of successive motions is not pursued; for the contraction of both auricles is simultaneous, as well as of the ventricles, while the dilatation and contraction of the auricles and ventricles are alternate to each other.

The quantity of blood propelled by each ventricular contraction cannot much exceed two ounces; the force by which the heart acts has been made a matter of mathematical calculations; but all these calculations, like the speculations of the chemical physiologist, cannot fail to be erroneous, while the peculiar nature of the vital force and action is disregarded. Keil estimated the power of the heart to be some ounces, while Borelli calculates it at 180,000 pounds!

Dr. Harvey, the discoverer of the circulation, conceived the whole of the circulatory process to be effected by the heart; in this, however, he was erroneous, for the function is likewise greatly dependant upon—

The action of the arteries. These vessels, as it respects the number, distribution, and coats, have already been described in ANATOMY. It is a remarkable fact, as stated by Mr. J. Hunter, that the elastic power is almost the only one with which the parietes of the larger arteries are furnished; while in those of smaller diameters, muscularity or irritability predominates: and that this last in the capillary vessels exists almost exclusively. "Thus the passage of the blood into the large trunks in the vicinity of the heart is principally occasioned by the propulsion communicated by this organ; and the circulation in the large vessels, as mentioned by Lazarius, is rather an hydraulic than a medical phenomenon; but in proportion as it becomes distant from the centre several causes retard it; and the blood could not arrive at every part, were not the arteries, which are more active in proportion to their smallness and distance from the heart, to act and propel it towards all the organs." (Richerand.) So erroneous was the opinion of Dr. Harvey.

The mechanical sources of the blood's retardation are, 1st, increase of space occupied by the arteries; for the collection of all the branches from a trunk would form a larger area than that of the parent branch. 2d, The resistance made by the curvatures of the arteries; this mechanism, its cause and effect, are beautifully illustrated in the tortuous course observed in the internal carotid which goes to the brain; by such mechanism an inordinate flow of blood into this organ is in a great measure obviated. 3d, Friction is said to impede the blood's motion; and lastly, its course is retarded by the angular distribution of the arterial ramifications.

The pulse of the arteries is vulgarly attributed to the alternate contractions and dilatations of the heart; but it is principally occasioned by that portion of the blood which is propelled into the aorta, coming in contact with the antecedent columns (for the arteries are always full), and thus communicating an impulse; but being obstructed by this resistance, it forces itself against the sides of the vessels, and gives them their pulsatory motion.

The pulse is more frequent in children, in females, and in persons of much irritability. In man, and individuals who are characterized by strength and regularity of excitement, it is less frequent but more vigorous. In early infancy, the pulsations are from 120 to 150 in a minute; towards the end of the second year, they are about 100; at puberty 80, manhood 70 to 75, and in elderly persons 60 or under. There are great varieties in this respect; Mr. Astley Cooper mentions in his lectures having seen an adult with a natural pulse as low as 27, and it sometimes is more than 100.

Capillary vessels. Arteries are described by some physiologists as terminating in anastomosis, in exhalants, in veins, in cellular texture, and in glands; others view the only proper terminations of these vessels to be that of their continuation into veins, which are connected with the arteries by the intervention of the capillary vessels. "The origin of the veins is only from the most minute extremities of the arteries, which are become capillary from the great number of divisions, and return upon themselves with a change of structure."

Dr. Harvey supposed that this communication was effected by an intermediate cellular substance; this, however, is the case only in some parts of the body, as in the placenta, the spleen, and corpora cavernosa penis.

In the capillary vessels the colour of the blood is lost, there not being here a sufficient mass of fluid to circulate such a collection of red globules as is necessary to constitute redness.

Action of veins. The venous is much more capacious than the arterial system of vessels. "It is estimated that out of twenty-eight or thirty pounds of blood, which is about the fifth part of the weight of the body in an adult man, nine parts are contained in the veins, and four only in the arteries."

In the arteries the circulation is effected by the action of the heart, or of their own muscular and contractile power; in the veins, however, these circulatory powers have so trivial an energy, that nature has guarded against impediments in the course of the blood through these last, in some instances, indeed, has facilitated this course, by such a distribution of the vessels as shall ensure an action of the muscles in propelling the vital fluid. The motion too of the neighbouring arteries assists the venal circulation, as also the valves, in like manner with those of the lymphatics, which divide the column of fluid into a number of small streams, equivalent to the diameters of the spaces thus formed.

Although on account of the comparative tardiness of venal circulation, and its not having such obstacles as arterial, there is no pulse in the veins; yet, in the vicinity of the heart, a species of undulatory motion is communicated to these vessels, principally occasioned by the reflux of blood before spoken of.

Demonstrations of the circulation. If an artery is opened, the blood is thrown out from the side next the heart; if a vein is pierced, the contrary is observed. If, again, a ligature is made on an artery, the course of the blood is arrested above the ligature; if on a vein, below it. Moreover in the semi-transparent vessels of frogs and some other animals, the direct passage of the blood from the heart to the arteries, and thence to the veins, may be actually seen by the aid of a microscope.

Of the blood.

The blood circulating in its vessels has the character of an homogeneous fluid; when separated, however, from the body, or withdrawn from the sphere of vital influence, it shortly divides itself into different parts. Immediately upon separation it exhales a strong vapour, to the presence of which have, with some inaccuracy of language, been attributed all its vital properties. After remaining a short time at rest, the blood separates into two distinct parts: the serum, which, according to the experiments of modern chemists, holds dissolved albumen, gelatine, soda, phosphat and muriat of soda, nitrat of potash, and muriat of lime; and the crassamentum, consisting of the colouring part, which is considered as an albumen more oxygenated and more concrescible than that of serum, holding in solution soda, phosphat of lime, and an excess of iron. Secondly, of the fibrine, formerly called coagulable lymph, which has a considerable analogy to muscular fibre, and when distilled gives out a great quantity of ammoniacal carbonat.

The above principles exist in the blood in a greater or diminished proportion, according to the constitution and health of the individual. In pale dropsical habits the serum is by far more considerable in quantity than its other parts; while the oxygenated albumen, or colouring part containing iron, is under these circumstances deficient. In diseases attended with high excitement, the fibrine is in greatest proportionate abundance.

The order we have observed would now lead us to describe the respiratory process, and the several purposes it serves in the animal economy; to notice in detail the action of the thorax, of the lungs, the alteration of air effected by respiration, the consequent alteration in the blood, and the disengagement of animal heat; for these particulars, however, we refer to the article RESPIRATION, and proceed to enquire into the function—

Of secretion.

Secretion is that process by which is separated from the blood-vessels generally, but in one or two instances, directly from the lymphatics, every species of animal fluid. These are divided by Fourcroy, and other physiologists, into, 1st, the saline, as the sweat and urine; 2d, the oleaginous, or inflammable, as the fat cerumen of the ears, &c. 3d, the saponaceous, as bile and milk; 4th, the mucous, as those which are found on the surface of the intestines; 5th, the albuminous, among which is classed the serum of the blood; 6th, the fibrous, another part of the last-mentioned fluid.

One of the most important and astonishing facts connected with secretion is, that from precisely the same fluid (the blood), are elaborated fluids of a nature widely different from each other, as well as from that whence they proceed. Thus, what can be more unlike than the urine and the blood from which it is prepared; or than the urine itself, and every other secretion? This variety of result, like others, has been referred to a mechanical filtration, and to chemical action; but a knowledge of the mechanism of the different glandular organs, still leaves us ignorant of the actual manner in which is operated this extraordinary change of combination. Secretion is, therefore, a vital action; and with this, as an ultimate fact, the physiologist must rest contented, while he is justified in instituting a research respecting the chemical composition of the fluids formed, and in tracing, as accurately as may be, the steps of their formation.

Secretory processes are divided into three kinds: 1st, serous transudation, which is effected by a mere termination of arteries on the surfaces upon which the fluid is poured out, without any intermediate structure; as on the surface of the body, furnishing the sweat; and on the membranes of joints, furnishing the lubricating fluids of these organs. 2d, Secretion by follicles, cryptæ, or lacunæ, which are supplied with a great quantity of vessels and nerves terminating on their surfaces, and an excretory duct originating from the follicles, &c. in the form of a vas efferens. This kind of gland is found in the ear, in the tonsils, and in all parts which secrete mucus. The more complicated glands which serve for the third kind of secretion, are visceral masses, constituted of an assemblage of nerves, and all kinds of vessels, disposed in packets, and united together by cellular membrane. These are called conglomerate glands; those of a more simple and smooth structure are named conglobate.

Secretion of the fat. Every fibre of the body is connected, and every organ enveloped by cellular texture. This membrane, however, does not merely serve the purpose of connection and envelopment, it is likewise the secretory organ of the adeps, which is found enclosed in separate cells in almost every part of the body. During life this substance is in a state of semifluidity, but concretes after death from the cessation of vital action, and the immediate reduction of animal temperature. The secretion of fat, both as to quantity and, in some measure, as to quality, is differently regulated at different periods of life, in different parts of the body, and under various circumstances of health. In early life the secretion is more abundant immediately under the skin; hence the plump appearance of infants. In more advanced years the surface of the body is almost destitute of adeps, while the tendency to its deposit is more internal. In an adult man in health, the adipose substance is averaged at about the twentieth part of the body's weight.

A chemical analysis of this fluid, proves it to partake more of those principles which are generally predominant in vegetable fluids, than other animal secretions; that is, it contains but a small proportion of azote, and an abundance of hydrogen and carbon. This circumstance, with the phenomena accompanying its deposit and reabsorption, seem to favour the supposition of its being "a kind of intermedium for a portion of the nutritive matter extracted from the food, through which it must necessarily pass before it is assimilated to the individual, of which it is destined to repair the loss." Thus an individual with much fat is able to abstain from food much longer than another without this supply, and, during such abstinence, the collected fat is rapidly reabsorbed.

Adeps, however, serves other purposes in the animal economy. Fat persons suffer less from cold than others; this appears to arise from animal oil being a bad conductor of caloric. It serves likewise to facilitate motion, and by surrounding the extremities of the nerves, obviates inordinate sensibility.

Of nutrition.

Digestion, by which the aliment received into the stomach is deprived of its nutritious particles; absorption, which conveys such nutritious portions into the fluids; and the circulation, by which it is further conveyed to the respective parts in order to undergo depuration by the various secretory organs; are all preliminary and subservient to the function now to be considered.

The indivisibility and individuality of the living body can only be maintained by an incessant change of the particles which enter its composition. "Thus the animal machine is continually destroyed, and at distant periods of life does not contain a single particle of the same constituent parts." The most commonly adduced evidence in favour of which, is the effect resulting from feeding animals with madder; for during the time that this substance is made part of the food, the bones become of a red colour, which is again lost if the madder is only for a short time suspended: proving that there is a constant decomposition and reformation even of those portions of the frame, which, from their compact texture, must be supposed the least susceptible of change. As then the parts of the body are constantly destroyed, new parts of the same nature are as constantly required, and to supply this demand is the office of nutrition. "A bone, for example, is a secretory organ that becomes incrusted with phosphat of lime: the lymphatic vessels, which in the work of nutrition perform the office of excretory ducts, remove this salt after it has remained a certain time in the areolæ of its texture. It is the same in muscles with respect to fibrine, and in the brain with albumen." We, therefore, find animal nutrition and organization, to consist in this: that the aliments having been converted first into chyle, and then into blood, and from this last having been furnished the various parts, solid and fluid, of which the animal is composed, such parts are at length separated by the peculiar action of their respective organs: thus the body is supported by intussusception as it has been denominated; a process very far different from that union effected by mechanical juxtaposition of particles, or operated by chemical affinity.

It has ever been the aim of the physiologist, more especially of recent times, to detect the prime, and, in a manner, common principle subservient to nutrition, in order to estimate the proportionate quantity of nutrient matter furnished by different alimentary substances. We must, however, assiduously guard against that fallacy which would connect itself with our inferences from viewing the process of nutritive elimination as a process merely of chemistry. The separation and assimilation of nutritive matter, may be pronounced to have greater reference to vital action than even to the substances themselves from which nutrition is extracted. For example: Let us suppose, with Dr. Cullen and many others, that the common principle drawn from alimentary matter is saccharine; let it even be demonstrated that such is the case; it by no means thence follows that the administration of saccharine matter in any form would be the mean of conveying into the system the largest portion of nutrition.

This doctrine it will not be improper further to illustrate, by calling the reader's attention to circumstances connected with one or two chronic maladies. Diabetes, whether originating from a disordered state of the assimilative organs, from an improper action of the kidneys, or, as appears most probable, from the conjunction of these two, is occasioned more immediately, or at least the emaciation which characterizes it, by a deprivation of saccharine matter from the frame; but the remedy for diabetes is not of a saccharine nature: on the contrary, if the disease admits of cure, such cure appears to be best ensured by an abstinence from all vegetable diet, by the exclusive use of animal food, and by the administration of certain astringent medicines. Again, in the rickets of infancy, which has an unquestionable dependance upon a loss to the bones of their due portion of phosphat of lime, the physician's object is not immediately to convey this matter into the blood, but to restore that degree and kind of excitement in the osseous vessels, from which the secretion results; and this will be effected by materials widely different, both in composition and abstract agency, from the substance, the deficiency of which is to be remedied. What quantity of phosphat of lime is discoverable by the chemist in the common chalybeate preparations, or in the nutritive aliment, which, properly administered, prove of such obvious and extensive utility in the management of the complaint in question? Hence, in another place, we were induced to remark, that the proximate cause of rickets does not so properly consist in "a deficiency of that matter which should form the solids of the system," as a deficiency of that excitation upon which the formation and deposit of such matter are momentarily dependant. See INFANCY.

M. Richerand, in his excellent work on physiology, states that "the marine plant, the ashes of which form soda, if sown in a box filled with earth that does not contain a particle of that alkali, and moistened with distilled water, furnishes it in as great quantity as if the plant had been growing on the borders of the sea, in a swampy soil, always inundated by brackish or salt water." Now what would follow a deprivation for a time of oxygen, light, or water, from such plant? Certainly a debilitated action, and consequent interruption of function. To remedy the disorder thus produced, we should not, however, apply to the plant the matter of which itself is composed; but restore those agents, through the medium of which it had preserved its due vitality. Have not these facts of the subserviency of vital support to vital action, been too much overlooked in the recommendation and imagined modus operandi of some medicines of modern physicians? When Dr. Darwin inferred that calcareous earth contributes to the nourishment of animals and vegetables, because "whatever has composed a part of an animal or vegetable, may again, after its chemical solution, become a part of another vegetable or animal," was not this vital agency and power of actually converting materials into those of an opposite nature, in some measure disregarded? But this is not the place for speculation. It is our business rather to compress than dilate: and we shall conclude by observing, that the principle now contended for, however important, is not to be received or acted upon, either in articles of food or medicine, in an unqualified or unlimited sense. A due supply of appropriate fuel as well as of stimulus, is necessary to support the flame of life. See MATERIA MEDICA.

It will be proper before quitting this subject, to observe, that as animal matter has been proved principally to differ from vegetable, in containing a larger proportion of azote than the latter, and the vital process of nutrition or animalization, however effected, has been judged to be a species of azotification, the following extract on this subject is given from the work just alluded to of M. Richerand: "Hallé believes that the hydro-carbonated oxide, or principle of nutrition, is combined with oxygen in the stomach and intestinal canal; whether the latter principle is introduced with the food into the primæ viæ, or furnished by the decomposed humours. The intestinal fluids suffer their azote to be disengaged, which is carried to the alimentary base, and replaces the carbon that had been attracted by oxygen to form the carbonic acid. This gas, when in the lungs, and again subjected to the action of atmospheric oxygen, carries off a certain portion of its carbon; and as it disengages the azote from venous blood, it effects a new combination of this principle with the chyle; and when propelled to the skin, the atmospheric oxygen again disengages its carbon, and completes its azotification. Perhaps even the cutaneous organ answers similar purposes to the lymphatic system, as the pulmonary organ may effect to the sanguiferous system."

It will be obvious to the reader, that the above theory supposes nutrition to consist in the constant loss of carbon, and constant supply of azote. It is admitted, however, not to account for the formation of phosphoric salts, adeps, and many other substances. It is, therefore, at least defective.

ON SENSATIONS.

The arrangement we have adopted now leads us to notice those functions "which connect us with surrounding objects;" and it was our original design in the present article to have treated at length on the physiology of the senses, especially of sight and hearing. As these last subjects, however, could not be made interesting or even intelligible, without connecting them with the philosophy of light and of sound, it has been judged more expedient, in order to avoid repetition, to confine their consideration exclusively to the articles OPTICS and SOUNDS. The anatomy of the organs will be found under the article ANATOMY.

Of smell. As the expansion of the optic nerve into the retina, constitutes the immediate instrument of vision, by being peculiarly invested with the faculty of perceiving light; as the portio mollis of the auditory nerve, is in like manner the direct medium for transmitting the sensation of sounds to the sensorium commune; so the organ of smell, constituted by a distribution of the olfactory nerves on that membrane which lines the nasal fossæ, is formed to receive, exclusively, the sensation of odours. It is apparently in proportion to the depth and extent of these fossæ, (affording a larger surface to the pituitary membrane,) that the perception of smell is variously regulated in different animals, and in some measure in different individuals of the same species; and the membrane itself requires to be in a perpetual state of moisture.

It is supposed by some that the olfactory nerves do not extend into the sinuses, but that these cavities merely assist the sense by longer retaining a greater mass of air, which is loaded with those odoriferous particles that constitute the exciting cause of this perception. The nasal organs are supplied with numerous small branches arising from the fifth pair of cerebral nerves; but these branches do not, according to M. Richerand, answer any further end, than that of contributing to general sensibility. The excitability to odours exists, according to our author, exclusively in those which are commonly denominated olfactory nerves.

Of taste. Every sense has been said to be strictly a modification of feeling: that of taste, however, approaches nearer than any other of the senses, even in its organization, to that of simple or proper fe eing; the surface of the tongue, which is the principal residence of this perceptibility, only varying from the common integuments in being thinner, more vascular, and having cryptæ, or follicles, which secrete the mucus of the tongue. These are situated in greatest number near its tip, and are erected "when we masticate high-flavoured food, or have a strong desire for any savoury dish." "It is observed that the sense of taste in different animals is more perfect in proportion as the nerves of the tongue are larger, the skin finer and more moist, its texture flexible, surface extensive, motions more easy and varied. The sense of taste in man would, perhaps, be more delicate than that of any other animal, if he was not to blunt its sensibility early in life by strong drinks, spicy ragouts, and all the refinements of luxury that are daily invented." "Is the lingual branch of the fifth pair of nerves alone adapted for the perception of taste? Do not the ninth pair equally serve for the same purpose?" This last question of M. Richerand has, we believe, generally been answered in the negative. It is from the fifth pair that the cryptæ, just spoken of, are supplied.

On touch. This has been with some propriety denominated the elementary sense, and all others considered as merely modifications accommodated to certain properties of bodies. "Every thing that is not light, sound, odour, or savour, is appreciated by the touch." This sense resides throughout the whole extent of the nervous system; the peculiar organ, however, of touch, or that by which we come to a knowledge of the qualities of objects, is the cutis, spread over the external surface of the body. In some part, this sense is peculiarly modified; in the skin, for example, covering the apices of the fingers; and in such parts we meet with something resembling the papillæ on the tongue; but, perhaps, not exactly similar, as they are rather constituted of nervous projections, than of glandular cryptæ: they are surrounded by an extremely fine vascular membrane. When the sense of feeling is exercised, these papillæ are supposed to swell and elevate the epidermis, which in itself is totally insensible to all such stimuli as act exclusively on living fibre. The epidermis, like the nails and hair, which last proceed from it, is a mere defence of the body, unorganized, and consequently destitute of excitability.

Action of the nerves. On this subject every thing is conjectural. We have not in this instance the assistance of anatomy for any thing farther than the fact, that the nerves are the organs through which the sensitive faculty is developed. The form, appearance, and mode of attachment of the nerves, are sufficient evidences that they do not act as vibratory chords, according to the supposition of some theorists; that they are tubes for conveying a fluid from and to the cerebral mass, is inconsistent with what has been discovered respecting the minuteness of divisibility in their fibrillæ; it likewise appears incompatible with what may be called the reacting communications between the centre or centres of sensation, and the sensitive organs: and we have already had occasion to say, that the extensive and very important discoveries of modern chemistry, have only brought us acquainted with a greater number of exciting agents; they do not appear to have cast any light upon the question respecting the actual mode of nervous or muscular excitation.

With respect to the analysis of our sensations, the production of ideas, and the comparative estimate of the human understanding with that of the instinctive and sensitive faculties of the inferior animals, we cannot be expected in this place to institute any inquiry. We must be content with expressing our opinion, that endeavours to establish an identity of faculty in the man and the brute (if the dispute is not a mere logomachy), have failed of their object; and as we believe that the fables of the Hamadryades are not realized in the "trees of our forests," "so we still flatter ourselves, notwithstanding the in dications of reason, and the great powers of imitation which have been exhibited by some individuals of the ape species, that the human intellect is of a nature essentially different from that of the monkey."

Of sleep, dreaming, somnambulism, sympathies, habit. The condition and the exciting causes of sleep, need no description; its proximate cause must necessarily lie in the same obscurity with those of other brainular and nervous affections. The artificial sleep which has been procured by pressure on the brain, proves nothing with respect to the actual condition of this organ in the sleep of nature; it is rather apoplexy than sleep that is thus occasioned. With respect to the phenomena attendant upon sleep, it has been well observed, that "the human body presents with tolerable accuracy the model of the centripetal and centrifugal powers of antient philosophy. The motion of several of the systems that enter into its structure, is directed from the centre to the circumference; it is a true exhalation that expels the produce and continual destruction of organs; such is the action of the heart, arteries, and all secretory glands. Other actions, on the contrary, are directed from the circumference towards the centre; and it is by these means that we continually receive, from the aliments introduced into the digestive organs, the air that penetrates into the internal structure of the lungs, and surrounds the surface of the body, the elements of its growth and reparation. These two motions in an opposite direction, continually balance each other, and alternately preponderate according to age, sex, sleep, or waking. During sleep, the motions are directed from the circumference towards the centre (motus in somno intrò vergunt, Hippocrates); and if the organs that connect our intercourse with external objects, repose, the internal parts act with greater advantage." Hence our author would explain, or rather trace, the connection of repose with corpulence; and of inordinate mental or bodily exercise with leanness. Sleep may, indeed, be so indulged as to reduce man to a condition of mere brutal existence, as in a case related by the author of the above extract, that of a man sleeping five-sixths of the day, with a digestion always active and easy, and with "moral affections circumscribed in the desire of aliment and repose."

Dreaming is a state intermediate between sleep and waking. It is the continued activity of some organs while others are in a state of quietude; hence incongruous associations, and all their consequences. For somnambulism (sleep-walking), see *Incubus*, in MEDICINE. *Sympathies* are, 1st, between two organs which perform the same function, as between the kidneys; 2d, those which have been attributed to the continuity of membranes, as the pain in the glans penis from calculary affections of the bladder; 3d, from the extension of local irritation, in the manner that the excretory duct of the parotid gland occasions an irritation, which is propagated in its substance, and augments its secretion; 4th, exerted between parts which do not appear to be connected either by nerves, membranes, or vessels; as when the nostrils are irritated, the diaphragm contracts and occasions sneezing; 5th, those which are considered as resulting from the agency of the vital principle, as when the rectum contracts by the stimulus of excrement.

Habit. Of the power and influence of habit, every one is sensible. Its operation in the animal economy, in relation both to the pathology of disease and the practice of medicine, requires assiduous attention. For example: a premature propulsion of the fœtus disposes to a return of the same accident, at the same period of pregnancy; thus, at this time, especial care is requisite in order to obviate this acquired propensity.

The termination of life has been referred to the power of habit, blunting gradually, and at length destroying, susceptibility of impression from the agents by which the vital principle had hitherto been supported. "Life, dependant on the continual excitement of the living solid, by the fluids that are conveyed to it, ceases, because after being accustomed to the impressions that these liquids produce on them, irritable and sensible parts become at length no longer able to perceive them; their action, gradually destroyed, would, perhaps, revive, if the stimulating powers were to acquire additional force."

For a general view of the organs subservient to animal motions, (the next subject in the order of our arrangement) consult COMPARATIVE ANATOMY, Vol. I. page 414.

OF THE VOICE, AND SPEECH.

Voice is produced by that air which is expelled from the lungs, being made to vibrate in passing through the glottis.

"Do the different modifications of which the voice is susceptible depend on the largeness or smallness of the glottis, or on the tension and relaxation of the ligaments that form the sides of the aperture from the glottis into the mouth?" which last is, indeed, the true organ of this function; for when an opening is made in the larynx below it, no sound is produced by the passage of the air. It appears, however, that both the size of this opening, and the tense or relaxed condition of the parietes of the larynx, contribute to modify voice, or, as it has been expressed, that the larynx is both a wind and a string instrument; voice being always acute in females, and in young persons previously to the age of puberty, at which time the diameter of the aperture in males undergoes a remarkable enlargement, and the state of tension in the ligaments of the glottis is always in correspondence with the narrowness of this opening.

Voice has a further dependance upon the length of the trachea. "A singer who wishes to run through the whole gamut, by passing from the upper to the lower notes, evidently shortens the neck and trachea, but, vice versa, lengthens them to produce a contrary effect.

"The strength then of the voice depends upon the volume of air that can be expelled from the lungs, and on the greater or less power of vibration of which the parietes of the canal are possessed in its passing outwards. Birds, the body of which is mostly aerial, have a voice very strong when compared to their size; their trachea provided with a double larynx, is almost entirely cartilaginous, particularly in certain chattering birds, as the jay and some others; while it is nearly membranous in the hedgehog, the noise of which is almost imperceptible."

Speech is the prerogative solely of the human species. It is constituted by modifications which the voice is made to pass through, from the motions of the tongue, lips, &c. "The ape, in which these parts are formed as in man, would speak like him, if the air in passing out of the larynx did not rush into the hyothyroid sacs, in some animals membranous, but cartilaginous in others, and even osseous in the alouette or purr, whose howl is so hoarse and frightful. Every time the animal wishes to cry, these sacs become distended, then emptied, so that it cannot furnish the different parts of the mouth with sounds to be articulated."

Articulated sounds are constituted by vowels, the consonants are merely for the purpose of connecting vowels together. The utterance of consonants is necessarily more forced and unnatural than that of vowels; hence the superior harmony of those languages which have the greatest number of such letters, as in the ancient language of the Greeks, "quibus dedit ore rotundo musa loqui." Hor. Hence, on the other hand, the harshness of the German, Dutch, and other languages. "It would be difficult," says M. Richerand, "to accumulate a greater number of consonants in one word," (and, consequently, to select a word of more difficult pronunciation), "than is found in the proper name of a German, called Schmidtgen."

Singing, stammering, lisping, dumbness, and ventriloquism. Singing is performed by an enlargement or contraction of the glottis; by an elevation or depression of the larynx; by an elongation or shortening of the neck; by an accelerated, prolonged, or retarded inspiration; and by either long or short, and abrupt expirations. "The agreeableness then, or the justness of the voice, the extent and variety of inflexions of which it is capable, depend on the correct conformation of its organs, on the flexibility of the glottis, elasticity of its cartilages, and particular disposition of different parts of the mouth, nasal passages, &c. If the two halves of the larynx or nasal fossæ are unequally disposed, it is sufficient to occasion a defect in precision and neatness of the voice."

Stammering and lisping are occasioned by a tongue too large, its frænum being too long; and by deficiency or bad arrangement in the teeth. When the apex of the tongue is prevented from striking properly the fore part of the roof of the mouth, an inability is produced of pronouncing the letter *r*.

Natural dumbness is almost invariably consequent upon deafness, and does not arise from an inability to articulate, but from an entire ignorance of sounds. See DUMBNESS, and DEAFNESS.

For the nature of those sounds produced by the ventriloquist, see likewise the article VENTRILOQUISM.

OF GENERATION.

We now proceed to notice those functions which nature has provided for the preservation not of the individual but of the species.

Differences of the sexes. During infancy we find the general characters of sex comparatively so indistinct, that some writers have been disposed to refer the successive developement of the male and female peculiarities solely to the genital organs. "Propter solum uterum mulier est id, quod est." Van Helmont. It has, however, been well observed, that we find from birth an independant variety of conformation in the male and the female; the former having less mobility of constitution, and less delicacy and roundness of form than the latter. The muscles of man are larger and firmer, the asperities of the bones are observable in a greater degree, the clavicle is more curved, the shoulders broader, the pelvis smaller, and the thigh-bones have a more outward direction. It is well known to the anatomist, that by examining attentively the skeleton, even previously to the age of puberty, the sex may generally be traced.

Even venereal desires have been imagined by some physiologists to be evolved independantly of the evolution of the genital organs. M. Richerand, from Calliot, adduces the instance of a female, who, "when advanced to the age of twenty-one, wished to satisfy the desires of nature, but in vain, she having nothing but the vulva properly formed; a small canal about two lines in diameter occupied the place of the vagina, and terminated in a cul-de-sac, an inch in depth. The most attentive examinations made by introducing a catheter into the bladder, and the index into the rectum, could not find an uterus." In this instance, however, we are disposed to think that the defect was in the position and communication of the uterus, not in its total absence; for, as opposed to this example, we remember to have heard a celebrated anatomist relate that he dissected a female, who, without venereal desires, though she lived some time beyond the age of puberty, had every external and internal part of the uterine system in perfection, excepting the ovaria. "Nulla cupido est propter vitia organorum."

Hermaphrodism, in a proper sense, has never existed in man, nor even in the inferior animals, the structure of whose genital organs are in the smallest measure analogous to man. An imperfection of organs, so as to render the sex doubtful, has, indeed, in some very few instances presented itself; but not, as in many of the lower order of animals and plants, a capability of self-impregnation.

Some physiologists have endeavoured to trace an analogy between the sexual organization of the male and female, comparing the ovaria of the latter with the testicles of the former, the Fallopian tubes with the vasa deferentia, the uterus with the vesiculæ seminales, the clitoris and vagina with the penis. These resemblances are in some measure correct: thus, the ovaria and testicles both secrete a seminal fluid, the Fallopian tubes and vasa deferentia both convey such fluid into appointed reservoirs—the uterus in the female, and the vesiculæ seminales in the male.

The generative procees in man is effected by an elimination from the blood of the semen by the testicles; the semen immediately upon its secretion passes through the seminiferous ducts into the vasa deferentia, which, after entering the abdomen, terminate in the vesiculæ seminales, and there deposit their contents. These vesicles furnish reservoirs for the semen; and we find those animals that are destitute of them, dogs for example, continue a long time in sexual contact, on account of the semen, secreted during the act of copulation, being directly transmitted from the testicles. As the semen in man passes through the prostate gland, it is mixed with the mucus which this gland secretes, and, thus mixed, enters the urethra to be ejected.

With respect to the part which the female performs in the process of generation, the following questions have been proposed. "Does the ovarium secrete a liquor, that, mixing with the male semen, produces the new being? or is there detached from it, at the moment of conception, an ovum which is vivified by the semen?" "Whatever part," says M. Richerand, "is taken in this discussion, we shall be forced to admit that the ovarium prepares something essential to generation, since its removal renders the female sterile. It is doubtless, likewise," continues our author, "that this something furnished by the ovaries, passes through the Fallopian tubes into the uterus, which receives one of their extremities, while the other, large, expanded, and fringed at its margin, floats in the cavity of the pelvis, supported by a small duplicature of the peritoneum, but contracts on itself, is closely applied to the ovarium during coition, and then constitutes a direct channel between this organ and the internal part of the uterus. The external orifice of the Fallopian tube, or its fringed parts, has been found closely investing the ovarium in certain females opened immediately after copulation. It may happen from some organic defect that the Fallopian tube cannot embrace the ovarium. In dissecting a subject at La Charité, that had been sterile, I found the fringed margins, or expanded extremities of the tubes, adhering to the lateral and superior parts of the pelvis, so that it had been impossible for them to perform their motions."

Although the semen is conveyed into the uterus, the penis does not actually enter this cavity; it is prevented by the smallness of the os tincæ, and it would be difficult to conceive even the passage of the semen, "if we did not know that the uterus, during copulation, is irritated, kept in agitation, and attracts the semen by a real aspiration."

With regard to the theory of conception, the greatest obscurity prevails. Analogy with what is observed in inferior animals, furnishes the principal assistance to the physiologist in this particular. It is well known that eggs laid by a hen which has had no intercourse with the cock, are incapable of being hatched, although they contain the rudiments of the chick; hence it has been inferred, and almost demonstrated, that it is the office of the male in general to "furnish the vivifying principle; that is, to animate the individuals, the germs of which are produced by the female."

This fecundation of the ovum is supposed to be effected in the ovarium, the seminal liquor received into the uterus having passed hither through the Fallopian tubes. This last supposition, however, has not perhaps been fully verified.

In the ovaria, after each conception, a small body is found (corpus luteum), which Haller proved to be the remains of a vesicle ruptured at the moment of conception, and permitting its contents to escape. The matter then which thus escapes, constitutes the germ of the fœtus. It will be evident that the Fallopian tubes require to be pervious, in order that conception may take place. It is observed by Morgagni, that they are often closed in courtezans, in consequence of habitual excitement

"Semen, when examined by a microscope, exhibits animalcula with a round head and slender tail, that move with rapidity;" hence the curious conjectures of Lewenhock, Boerhaave, Cowper, and others, that every part of the seminal liquor is capable of becoming a being resembling that from which it was formed. "These animalcula pass in a current through the Fallopian tubes to the ovaria, where they enter into a violent contest, in which all are killed except one, which being left champion in the field of battle, penetrates into the ovarium destined to receive it." According to the hypothesis of M. Buffon, every part of the body furnishes its appropriate molecula to compose the semen; "and these atoms coming from the eyes, ears. &c. of the man and woman, arrange themselves round the internal mould, the existence of which he admits, believes it to form the base of the edifice, and to arise from the male, if it should be a boy, and from the female, if a girl."

If it was necessary to offer any objection to this fanciful hypothesis, it would suffice to say that infants are often born perfectly organized, the parents of whom have had defects in structure.

For the history of gestation, delivery, &c. consult the article MIDWIFERY.

On ages, temperaments, varieties in the human species, &c.

The last subjects treated of by M. Richerand, very little remains to be said of in the present place.

Of infancy, its peculiarities and diseases, see the article INFANCY. The process of dentition for the most part commences towards the end of the seventh month, earlier or later, according to the constitution of the infant. The middle incisores of the upper jaw are the first to appear; shortly afterwards the incisores of the inferior maxilla; then the lateral incisors of the upper, afterwards of the under jaw; then the canine teeth in the same order; and between eighteen months and two years, but in the inverse order, the molares. This completes the first dentition. Towards the end of the fourth year, two other molares come to be added. These last remain during life, but the first teeth fall out nearly in the order of their appearance, and are succeeded by others larger and better formed. Towards the ninth year, two additional large molares appear beyond the former; and between the ages of eighteen and thirty, two teeth perforate the gums at the extremity of the alveolar processes: these are the dentes sapientiæ.

Each row of teeth exists at the same time in the maxillæ of the fœtus, each alveola containing two membranous follicles. That which is to constitute the primary tooth first swells, a calcareous matter encrusts on its surface and forms the body of the tooth, by which the follicle is obscured which secretes the osseous part, so that when the small bone is fully formed, the membranous vesicle on the sides of which the dental vessels and nerves are spread out, is in the centre of its body, and adheres to the parietes of its internal cavity.

Ossification is effected by a deposit of bony matter, (which, as we have already observed, is principally formed of phosphat of lime,) in the centres of the cartilages, which gradually proceeds to their extremities or circumferences. Although ossification is some years before it is completed, there has been sufficient bony matter deposited in the cartilages, to enable the child to stand and walk, in the course of twelve months, or less, from birth. "The vital motions of infancy tend towards the head," hence the frequency of disease in this part.

Of puberty. In England the season of puberty is scarcely before the fifteenth year, sooner or later, according to constitutional variety. The principal marks of puberty in the male are the change of voice, which arises from a sudden dilatation of the aperture in the glottis, already spoken of. In females, the menstrual discharge forms the chief index of the change alluded to. This discharge is not a mere flow of blood as from ruptured vessels, but is a proper secretion from the arteries which terminate on the internal surface of the uterus. The final cause of menstruation is unquestionably to furnish the fœtus with its requisite support during gestation. The hypotheses which have been proposed to account for menstruation, as the influence of the moon, &c. are too frivolous and antiquated to require refutation or notice.

The state of virility succeeds to that of puberty, and now the constitutional character is fully and firmly established. The antients, observing a great diversity among individuals, and supposing that such varieties must depend upon some elementary matter with which the body is impregnated, instituted a general division of constitution into four classes, which in compliance with their mode of judging respecting the origin of such differences they called temperaments; a word retained, while the theories which introduced it are abandoned. The sanguine, the melancholic, the choleric, and the phlegmatic constitutions of authors, with their endless intermixtures, do not require description in this place. M. Richerand has proposed a classification which will be seen by referring to the above table, and which is, perhaps, more accurate in relation to appearances, certainly much more so as it regards the origin of difference, than the ancient distinctions. We are persuaded, that to the physician, the arrangement of individual peculiarity would be most useful, which should be founded on those marks indicating an hereditary tendency to lymphatic, nervous, and sanguineous affections

The national varieties of man are, according to our author, the Arab-European, "with face oval, or nearly oval, in a vertical direction, the nose long, the forehead projecting, hair long, and generally lank, skin more or less white." These fundamental characters are no where so well marked as in the north of civilized Europe.

The Mongol race, with "the forehead flat, the cranium not very prominent, the eyes directed a little obliquely outwards, and the oval formed by the face, instead of being from the forehead to the chin, is from one cheek to the other." This is the most numerous race, comprehending the Chinese, Tartars, Japanese, &c.

The Hyperborean race, "with flat face, squat body, and very short stature," is formed of the Greenlanders, Samoiedes, and Laplanders. The American Indian, M. Richerand conjectures to be a race from the other continents. On the Negro, he has the following remarks: "the small progress of this race in the study of the sciences and in civilization; their decided taste and singular aptitude for all the arts that require more address than understanding and reflection, as dancing, music, fencing, &c.; the form of their head, which is a medium between the European and orang-outang; the existence of intermaxillary bones, at an age when in us the traces of their separation are completely obliterated; the high situation and smallness of the calf of the leg, &c., have been advanced as arguments which, however, are less solid than specious, by those who have endeavoured to degrade this portion of the human species, with a view of justifying the commerce made of them by civilized nations, and the slavery to which they are reduced.

"Without admitting this position," says our author, "believed by the avarice of riches, we cannot but allow that the differences in organization induce (should he not have said, are accompanied with?) an obvious inequality in the perfection of the moral and intellectual faculties. This truth will be completely elucidated if we can point out their moral differences to be equally real and strongly marked as the physical characters of the human races that have been just recapitulated: oppose European activity, versatility, and restlessness, to Asiatic indolence, phlegm, and patience; examine what effects may be produced on the character of nations by the fertility of the soil, serenity of the atmosphere, and mildness of the climate; shew by what obligation of physical and moral causes the influence of custom has so much power over Eastern people, that in India and China we find the same laws, manners, and forms of worship, as existed long before the commencement of our æra; investigate by what singularity these laws, manners, and religions, have suffered no alteration amidst the revolutions that have so frequently overturned those rich countries, which have been several times conquered by the warlike Tartars; demonstrate that ignorant and ferocious conquerors, by the irresistible ascendancy of wisdom and information, have adopted the customs of the nations they have subjugated; and prove that the stationary state of the arts and sciences, in people who have enjoyed the benefits of society and the advantages of civilization before us, *is not so much to be attributed to the imperfection of their organization*, as to the humiliating yoke of a religion, abounding in absurd practices, and which makes learning the exclusive appendage of a privileged cast."

For physiology of plants, see PLANTS, *physiology of.*

PHYSSOPHORA, a genus of vermes mollusca; the generic character is, the body gelatinous, pendant from an aerial vesicle, with gelatinous members at the sides, and numerous tentacula beneath. These are nearly allied to the medusæ, and might without much impropriety be removed to that genus. There are three species.

PHYTEUMA, *cretic rampions*, in botany, a genus of the pentandria monogynia class of plants, the flower of which is composed of a single stellated petal; the fruit is a roundish capsule, and contains three cells, with numerous seeds. There are sixteen species.

PHYTOLACCA, in botany, a genus of the decandria decagynia class of plants, the corolla whereof consists of five roundish, hollow, patent petals; the fruit is an orbiculated depressed berry, with ten longitudinal furrows, and as many cells, in each of which is a single kidney-shaped seed. There are six species. In Virginia and other parts of America the inhabitants boil the leaves, and eat them in the manner of spinach. They are said to have an anodyne quality, and the juice of the root is violently cathartic. The stems when boiled are as good as asparagus. The Portuguese had formerly a trick of mixing the juice of the berries with their red wines, in order to give thema deeper colour; but as it was found to debase the flavour, and to make the wine deleterious, the matter was represented to his Portuguese majesty, who ordered all the stems to be cut down yearly before they produced flowers, thereby to prevent any further adulteration. The same practice was common in France till it was prohibited by an edict of Louis XVI. and his predecessor under pain of death. This plant has been said to cure cancers; but the truth of this assertion has not been indisputably proved, and does not appear very probable.

PHYTOLOGY, a discourse concerning the kinds and virtues of plants.

PHYTOTAMA, a genus of birds of the order passeres; the generic character is, bill conic, straight, serrate; nostrils oval; tongue short, obtuse; feet four-toed. There is only a single species, viz. P. rara, that inhabits Chili, nearly equal in size to the quail; has a harsh interrupted cry, resembling the syllables ra, ra; feeds on fresh vegetables which it cuts down near the roots with its bill as with a saw, and is on that account a great pest to gardens; builds in high shady trees, in retired places; eggs white spotted with red.

PIA MATER. See ANATOMY.

PICA. See MUS.

PICÆ, the second order of birds, according to the Linnæan system. They are distinguished by a bill sharp-edged, convex above; legs short, strong; feet formed for walking, perching, or climbing; body toughish, impure; food various, filthy substances; nest in trees; the male feeds the female while she is sitting. They live in pairs. Of this order there are twenty-six genera, viz. alcedo, buceros, bucco, buphago, certhia, coracias, corvus, crotophaga, cuculus, galbula, glaucopis, gracula, merops, momotus, oriolus, paradisea, picus, psittacus, rhamphastos, scythrops, sitta, todus, trochilus, trogon, upupa, yunx.

PICKET, PICKQUET, or PIQUET, in fortification, a painted staff shod with iron; used in marking out the angles and principal parts of a fortification, when the engineer is tracing out a plan upon the ground.

PICQUET, a celebrated game at cards played between two persons, with only thirty-two cards; all the twos, threes, fours, fives, and sixes, being set aside.

In playing at this game, twelve cards are dealt to each, and the rest laid on the table: when if one of the gamesters finds he has not court-card in his hand, he is to declare that he has carte-blanche, and tell how many cards he will lay out, and desire the other to discard, that he may shew his game, and satisfy his antagonist, that the carte-blanche is real; for which he reckons ten. And here the eldest hand may take in three, four, or five, discarding as many of his own for them, after which the other may take in all the remainder if he pleases. After discarding, the eldest hand examines what suit he has most cards of; and, reckoning how many points he has in that suit, if the other has not so many in that, or any other suit, he reckons one for every ten in that suit, and he who thus reckons most is said to win the point. It is to be observed, that in thus reckoning the cards, every card goes for the number it bears; as a ten for ten; only all court-cards go for ten, and the ace for eleven, and the usual game is one hundred up. The point being over, each examines what sequences he has of the same suit, viz. how many tierces, or sequences of three cards; quarts, or sequences of four cards; quintes, or sequences of five cards, &c. he has. These several sequences are distinguished in dignity by the cards they begin from: thus, ace, king, and queen, are stiled tierce major; king, queen, and knave, tierce to a king; knave, ten, and nine, tierce to a knave; and the best tierce, quarte, or quinte prevails, so as to make all others in that hand good, and to destroy all those in the other hand. In like manner a quarte in one hand sets aside a tierce in the other.

The sequences over, they proceed to examine how many aces, kings, queens, knaves and tens each holds; reckoning for every three of any sort three; but here too, as in sequences, he that with the same number of threes or fours, has one that is higher than any the other has, makes his own good, and sets aside all his adversary's; but four of any sort, which is called a quatorze, because fourteen are reckoned for it, always set aside three.

The game in hand being thus reckoned, the eldest proceeds to play, reckoning one for every card he plays above nine, while the other follows him in the suit: but unless a card is won by one above nine, except it is the last trick, nothing is reckoned for it. The cards being played out, he that has most tricks reckons ten for winning the cards: but if they have tricks alike, neither reckons any thing. If one of them wins all the tricks, instead of ten, which is his right for winning the cards, he reckons forty, and this is called capot.

The deal being finished, each person sets up his game: they then proceed to deal again as before; cutting afresh each time for the deal: if both parties are within a few points of being up, the carte-blanche is the first that reckons, then the point, then the sequences, then the quatorzes, then the tierces, and then the tenth cards. He that can reckon thirty in hand by carte-blanche, points, quintes, &c. without playing, before the other has reckoned any thing, reckons ninety for them, and this is called a repike; and if he reckons above thirty, he reckons so many above ninety. If he can make up thirty, part in hand, and part in play, before the other has told any thing, he reckons for them sixty; and this is called a pique, whence the name of the game. Mr. de Moivre, in his doctrine of chances, has resolved, among others, the following problems: 1. To find, at picquet, the probability which the dealer has for taking one ace or more in three cards, he having none in his hands. He concludes from his computation, that it is 29 to 28 that the dealer takes one ace or more. 2. To find at picquet the probability which the eldest has of taking an ace or more in five cards, he having no ace in his hands. Answer; 232 to 91, or 5 to 2, nearly. 3. To find at picquet the probability which the eldest has of taking both an ace and a king in five cards, he having none in his hand. Answer; the odds against the eldest hand taking an ace and a king are 331 to 315, or 21 to 20 nearly. 4. To find at picket the probability of having twelve cards dealt to, without king, queen, or knave; which case is commonly called cartes-blanches. Answer; the odds against cartes-blanches are 323 to 578,956, or 1791 to 1 nearly. 5. To find how many different sets essentially different from one another, one may have at picquet before taking in. Answer; 28,967,278. This number falls short of the sum of all the distinct combinations, whereby twelve cards may be taken out of 32, this number 225,792,840; but it ought to be considered, that in that number several sets of the same import, but differing in suit, might be taken, which would not introduce an essential difference among the sets.

PICRAMNIA, a genus of the pentandria order, in the diœcia class of plants; and in the natural method ranking with those that are doubtful. The calyx is tripartite; the corolla has three petals; the stamina from three to five, awl-shaped, and seem to join together at the base; there are two styli, which are short and bent backwards; the berry is roundish, and contains two oblong seeds, and sometimes one seed only. There are two species: The antidesma, or murjoe bush, is frequent in copses and about the skirts of woods in Jamaica, rising about eight or nine feet from the ground. The leaves are of an oval form, pointed, and placed in an alternate form along the branches; the flower-spikes are long, pendulous, and slender; the florets small and white: the berries are numerous, at first red, then of a jet black colour; the pulp is soft, and of a purple complexion. The whole plant is bitter, and especially the berry. The negroes make a decoction of them, and use it in weaknesses of the stomach and in venereal cases.

PICRIS, *ox-tongue*, a genus of the polygamia æqualis order, in the syngenesia class of plants. The calyx is calycled; receptacle naked; seed transversely grooved; down feathered. There are six species, of which the most remarkable is the echioides, or common ox-tongue, growing spontaneously in corn-fields in Britain. It has undivided leaves embracing the stem, with yellow blossoms, which sometimes close soon after noon, at other times remain open till nine at night. It is an agreeable pot-herb while young. The juice is milky, but not too acrid.

PICRIUM, in botany, a genus of the monogynia order, in the tetrandria class of plants; and in the natural method ranking with those that are doubtful. The calyx is monophyllous and quinquefid; the corolla monopetalous, and its tube is short; the filaments are four in number, and hooded at the place of their insertion; the style long and thick; the stigma bilamellated; the capsule is round, bivalved, and contains a number of small seeds. There are two species, viz. the spicatum and ramosum; both natives of Guiana. Both species are bitter, and employed in dyspepsy, and to promote the menses: they are also recommendeded in visceral obstructions.

PICUS, the *woodpecker*, in ornithology, a genus belonging to the order of picæ. The beak is straight, and consists of many sides, and like a wedge at the point: the nostrils are covered with bristly feathers; the tongue is round like a worm, very long, and sharp at the point, which is beset with bristles bent backwards. See Plate Nat. Hist. fig. 337.

The grand characteristic of these birds is the tongue, the muscles necessary to the motions of which are singular and worthy of notice, affording the animal means of darting it forwards the whole length, or drawing it within the mouth at will. Latham enumerates no less than fifty different species of woodpeckers, besides varieties of some of them which amount to nine more. The most remarkable are as follows:

1. The picus martius, or greatest black woodpecker, is about the size of a jackdaw, being about 17 inches long; the bill is nearly two inches and a half in length, of a dark ash-colour; the whole bird is black, except the crown of the head, which is vermilion. The female differs from the male in having the hind head only red, and not the whole crown of the head; and the general colour of the plumage has a strong cast of brown in it. It has likewise been observed, that the red on the hind head has been wholly wanting; and indeed both male and female are apt much to vary in different subjects, some having a much greater proportion of red on the head than others. This species is found on the continent of Europe, but not in plenty except in Germany.

It is said to build in old ash and poplar trees, making large and deep nests; and Friesch observes, that they often so excavate a tree, that it is soon after blown down with the wind; and that under the hole of this bird, may often be found a bushel of dust and bits of wood. The female lays two or three white eggs, the colour of which, as Willughby observes, is peculiar to the whole woodpecker genus, or at least all those which have come under his inspection.

2. The picus principalis, or white-billed woodpecker, is somewhat bigger than the last, being equal in size to a crow. It is sixteen inches long, and weighs about twenty ounces. The bill is white as ivory; the head itself, and the body in general, are black.

This species inhabits Carolina, Virginia, New Spain, and Brazil: and is called by the Spaniards carpenter, and not without reason; as this as well as most of the other species make a great noise with the bill against the trees in the woods, where they may be heard at a great distance, as if carpenters were at work; making, according to Catesby, in an hour or two, a bushel of chips.

3. The picus erythrocephalus, or red-headed woodpecker, is about eight inches three quarters long, and weighs two ounces. The bill is an inch and a quarter in length, of a lead-colour; the head and the neck are of a most beautiful crimson; the back and wings are black; the rump, breast, and belly are white. The cock and hen are very nearly alike.

This species inhabits Virginia, Carolina, Canada, and most of the parts of North America; but at the approach of winter, it migrates more or less to the southward, according to the severity of the season; and upon this circumstance the people of North America foretel the rigour or clemency of the ensuing winter. During the winter they are very tame, and are frequently known to come into the houses in the same manner as the redbreast is wont to do in England. It is observed that this species is found chiefly in old trees; and the noise they make with their bills may be heard above a mile distant. It builds the earliest of all the woodpeckers, and generally pretty high from the ground. It is accounted by many people very good eating.

4. The picus pubescens, or little woodpecker, weighs only one ounce and a half. The top of the head is black, and on each side above the eye is a white line; the hind head is red; the hind part of the neck, the back, and rump, are black, which is divided into two parts by a line of white passing down the middle to the rump. The female has no red on the hind head. It abounds in New Jersey, where it is esteemed most dangerous to orchards, and is the most daring. As soon as it has pecked one hole in a tree, it makes another close to the first, in an horizontal direction, proceeding till it has made a circle of holes quite round the tree; and the apple-trees in the orchards have often several of these rings of holes round the stem, insomuch that the tree frequently dries up and decays.

5. The yellow woodpecker is about nine inches long. The hind head is crested; the head itself, the neck, and whole body, are covered with dirty-white feathers; from the lower jaw to the ears, on each side, there is a red stripe. This species is common at Cayenne, and is called there charpentier jaune. It makes its nest in old trees which are rotten within. The note of this bird is a kind of whistle six times repeated, of which the two or three last are in a graver accent than the others. The female wants the red band on the side of the head which is seen in the male.

6. The viridis, or green woodpecker, weighs six ounces and a half; its length is thirteen inches, the breadth twenty and a half; the bill is dusky, triangular, and near two inches long; the crown of the head is crimson, spotted with black; the eyes are surrounded with black, and the males have a rich crimson mark beneath the blackness; the rump is of a pale yellow; the whole of the under part of the body is of a very pale green. These birds feed entirely on insects; and their principal action is that of climbing up and down the bodies or boughs of trees. This species feeds oftener on the ground than any other of the genus: all of them make their nests in the hollows of trees; and lay five or six eggs, of a beautiful semi-transparent white. The young ones climb up and down the trees before they can fly. It is common in England.

7. The major, or great spotted woodpecker, weighs two ounces three quarters; the length is nine inches; the breadth is sixteen. The forehead is of a pale buff-colour; the crown of the head a glossy black; the hind-part marked with a rich deep crimson spot. The cheeks are white, bounded beneath by a black line that passes from the corner of the mouth and surrounds the hind part of the head. The neck is encircled with a black colour. The throat and breast are of a yellowish white; the vent-feathers of a fine light crimson. The back, rump, and coverts of the tail, and lesser coverts of the wings, are black; the scapular feathers and coverts adjoining to them are white. The quill-feathers are black, elegantly marked on each web with round white spots. The female wants the beautiful crimson spot on the head: in other respects the colours of both agree. This species is much more uncommon than the preceding, and keeps altogether in the woods. This bird is found in England, France, and Germany, and other parts of Europe, frequenting the woods like the rest of its genus, and is likewise met with in America. It is a very cunning bird; for, when a person has seen one on a tree, he is almost sure to lose sight of it, if the tree is large, and the observer not very attentive; for, the moment it spies any one, it will creep behind a branch, and there lie secure till the danger is over.

PIEPOUDRE *(Court of)*, the lowest, and at the same time the most expeditious, court of justice known to the law of England. It is called piepoudre (curia pedis pulverisati) from the dusty feet of the suitors. But the etymology given us by a learned modern writer is much more ingenious and satisfactory; it being derived, according to him, from pied puldreaux, "a pedlar," in old French, and therefore signifying the court of such petty chapmen as resort to fairs or markets. It is a court of record, incident to every fair and market; of which the steward of him who owns or holds the toll of the market is the judge. It was instituted to administer justice for all commercial injuries done in that very fair or market, and not in any preceding one; so that the injury must be done, complained of, heard, and determined, within the compass of one and the same day, unless the fair continues longer. The court has cognizance of all matters of contract that can possibly arise within the precinct of that fair or market; and the plaintiff must make oath that the cause of action arose there. From this court a writ of error lies, in the nature of an appeal, to the courts at Westminster.

PIGEONS. Every person who shall shoot at, kill, or destroy a pigeon, may be committed to the common jail for three months, by two justices of the peace, or pay 20*s.* to the poor. 1 Jac. I. c. 27.

PIKE, an offensive weapon, consisting of a shaft of wood, twelve or fourteen feet long, headed with a flat-pointed steel, called the spear. The pike was a long time in use among the infantry, to enable them to sustain the attack of the cavalry; but it is now taken from them, and the bayonet, which fixes on at the end of the carabine, is substituted in its place. Yet the pike still continues the weapon of the serjeants of foot, who perform no motions with it but in charging.

PILASTER. See ARCHITECTURE.

PILE, in artillery, denotes a collection or heap of shot or shells, piled up by horizontal courses into either a pyramidal or else a wedgelike form; the base being an equilateral triangle, a square, or a rectangle. In the triangle and square, the pile terminates in a single ball or point, and forms a pyramid.

In the triangular and square piles, the number of horizontal rows, or courses, or the number counted on one of the angles from the bottom to the top, is always equal to the number counted on one side, in the bottom row. And in rectangular piles, the number of rows, or courses, is equal to the number of balls in the breadth of the bottom row, or shorter side of the base; also in this case, the number in the top row, or edge, is one more than the difference between the length and breadth of the base.

The courses in these piles are figurative numbers.

In a triangular pile, each horizontal course is a triangular number, produced by taking the successive sums of the ordinate numbers, viz.

$$\begin{aligned} 1 &= 1 \\ 1+2 &= 3 \\ 1+2+3 &= 6 \\ 1+2+3+4 &= 10, \text{ \&c.} \end{aligned}$$

And the number of shot in the triangular pile, is the sum of all these triangular numbers, taken as far, or to as many terms, as the number in one side of the base. And therefore, to find this sum, or the number of all the shot in the pile, multiply continually together the number in one side of the base row, and that number increased by 1, and the same number increased by 2; then $\frac{1}{6}$ of the last product will be the answer, or number of all the shot in the pile.

That is, $\frac{n \cdot \overline{n+1} \cdot \overline{n+2}}{6}$ is the sum; where n is the number in the bottom row.

Again, in square piles, each horizontal course is a square number, produced by taking the square of the number in its side, or the successive sums of the odd numbers, thus,

$$\begin{aligned} 1 &= 1 \\ 1+3 &= 4 \\ 1+3+5 &= 9 \\ 1+3+5+7 &= 16, \text{ \&c.} \end{aligned}$$

And the number of shot in the square pile is the sum of all these square numbers, continued so far, or to as many terms, as the number in one side of the base. And therefore, to find this sum, multiply continually together the number in one side of the bottom course, and that number increased by 1, and double the same number increased by 1; then $\frac{1}{6}$ of the last product will be the sum or answer.

That is, $\frac{n \cdot \overline{n+1} \cdot \overline{2n+1}}{6}$ is the sum.

In a rectangular pile, each horizontal course is a rectangle, whose two sides have always the same difference as those of the base course, and the breadth of the top row, or edge, being only 1; because each course in ascending has its length and breadth always less by 1 than the course next below it. And these rectangular courses are found by multiplying successively the terms or breadths 1, 2, 3, 4, &c. by the same terms added to the constant difference of the two sides d; thus,

$$\begin{aligned} 1 \cdot \overline{1+d} &= 1 + d \\ 2 \cdot \overline{2+d} &= 4 + 2d \\ 3 \cdot \overline{3+d} &= 9 + 3d \\ 4 \cdot \overline{4+d} &= 16 + 4d, \text{ \&c.} \end{aligned}$$

And the number of shot in the rectangular pile is the sum of all these rectangles, which, it is evident, consist of the sum of the squares, together with the sum of an arithmetical progression, continued till the number of terms is the difference between the length and breadth of the base, and 1 less than the edge or top row. And therefore, to find this sum, multiply continually together the number in the breadth of the base row, the same number increased by 1, and double the same number increased by 1, and also increased by triple the difference between the length and breadth of the base; then $\frac{1}{6}$ of the last product will be the answer.

That is, $\frac{b \cdot \overline{b+1} \cdot \overline{2b+3d+1}}{6}$ is the sum;

where b is the breadth of the base, and d the difference between the length and breadth of the bottom course.

PILE, in building, is used for a large stake rammed into the ground in the bottom of rivers, or in marshy land, for a foundation to build upon.

PILE ENGINE. See ENGINE.

PILE, in coinage, denotes a kind of puncheon, which in the old way of coining with the hammer, contained the arms, or other figure and inscription, to be struck on the coin. Accordingly we still call the arms side of a piece of money the pile, and the head the cross; because in ancient coins, a cross usually took the place of the head in ours: but some will have it called pile, from the impression of a ship built on piles, struck on this side of our ancient coins.

PILLAR. See ARCHITECTURE.

PILOT, a person employed to conduct ships over bars and sands, or through intricate channels, into a road or harbour. Pilots are no constant and standing officers aboard our vessels, but are called in occasionally, on coasts or shores unknown to the master; and having piloted in the vessel, they return to the shore where they reside.

Pilots taking upon them to conduct ships up the Thames, are to be examined and approved by the master and wardens of the Trinity-house at Deptford, or shall be liable to forfeit 10*l.* for the first offence, and 20*l.* for the second, &c. and the like penalty, if they act without licence from the said master and wardens; and if by their negligence they lose a ship, they shall be for ever disabled. 3 Geo. I. and 5 Geo. II. c. 20.

PILULARIA, a genus of the cryptogamia filices. There is one species.

PIMELIA, a genus of insects of the order coleoptera. The generic character is, antennæ filiform; feelers four; thorax plano-convex, margined; head exserted; shells rather rigid; wings usually none. It is divided into sections: A, antennæ moniliform at the tip; B, entirely filiform.

PIMELITE, a mineral distinguished by a fine apple-green colour: according to Klaproth, it is composed of

35.00	silica
15.62	oxide of nickel
5.00	alumina
4.58	oxide of iron
1.25	magnesia
37.91	water.
99.36	

PIMENTA, or PIMENTO, *Jamaica pepper*, or *allspice*. See MYRTUS.

PIMPINELLA, *burnet saxifrage*, a genus of the digynia order, in the pentandria class of plants. The petals are bent in; stigma subglobular; fruit ovate, oblong. There are nine species; the most remarkable of which are: 1. The major, or greater burnet saxifrage, growing naturally in chalky woods, and on the sides of the banks near hedges, in several parts of England. 2. The ansium or common anise, an annual plant, which grows naturally in Egypt; but is cultivated in Malta and Spain, whence the seeds are annually imported into Britain.

Both these species are used in medicine. The roots of pimpinella have a grateful, warm, very pungent taste, which is entirely extracted by rectified spirit: in distillation the menstruum arises, leaving all that it had taken up from the root united into a pungent aromatic resin. This root promises, from its sensible qualities, to be a medicine of considerable utility, though little regarded in common practice: the only officinal composition in which it is an ingredient is the pulvis ari compositus. Stahl, Hoffman, and other German physicians, are extremely fond of it; and recommend it as an excellent stomachic, resolvent, detergent, diuretic, diaphoretic, and alexipharmic.

Aniseeds have an aromatic smell, and a pleasant warm taste, accompanied with a degree of sweetness. Water extracts very little of their flavour; rectified spirit, the whole. These seeds are in the number of the four greater hot seeds: their principal use is in cold flatulent disorders, where tenacious phlegm abounds, and in the gripes to which young children are subject. Frederic Hoffman strongly recommends them in weakness of the stomach, diarrhœas, and for strengthening the tone of the viscera in general; and thinks they well deserve the appellation given them by Helmont, intestinorum solamen. The smaller kind of aniseeds brought from Spain are preferred.

PIN, in commerce, a little necessary instrument made of brass wire, chiefly used by women in adjusting their dress. In the year 1543, by statute 34 and 35 of Henry VIII. cap. vi. it was enacted, "that no person shall put to sale any pinnes but only such as shall be double-headed, and have the heads soldered fast to the shank of the pins, well smoothed, the shank well shapen, the points well and round filed, canted, and sharpened." From the above extract it should appear that the art of pin-making was but of late invention, probably introduced from France; and that our manufactories since that period have wonderfully improved.

Though pins are apparently simple, their manufacture is, however, not a little curious and complex. When the brass wire, of which the pins are formed, is first received at the manufactory, it is generally too thick for the purpose of being cut into pins. The first operation therefore is that of winding it off from one wheel to another with great velocity, and causing it to pass between the two, through a circle in a piece of iron of smaller diameter: the wire being thus reduced to its proper dimensions, is straightened by drawing it between iron pins, fixed in a board in a zigzag manner, but so as to leave a straight line between them: afterwards it is cut into lengths of three or four yards, and then into smaller ones, every length being sufficient to make six pins; each end of these is ground to a point, which is commonly performed by boys, who sit each with two small grinding-stones before him, turned by a wheel. Taking up a handful, he applies the ends to the coarsest of the two stones, being careful at the same time to keep each piece moving round between his fingers, so that the points may not become flat: he then gives them a smoother and sharper point, by applying them to the other stone, and by that means a lad of twelve or fourteen years of age is enabled to point about 16,000 pins in an hour. When the wire is thus pointed, a pin is taken off from each end, and this is repeated till it is cut into six pieces. The next operation is that of forming the heads, or, as they term it, head-spinning; which is done by means of a spinning-wheel, one piece of wire being thus with astonishing rapidity, wound round another, and the interior one being drawn out leaves a hollow tube between the circumvolutions: it is then cut with shears, every two circumvolutions or turns of the wire forming one head: these are softened by throwing them into iron pans, and placing them in a furnace till they are red-hot. As soon as they are cold, they are distributed to children, who sit with anvils and hammers before them, which they work with their feet, by means of a lathe; and taking up one of the lengths, they thrust the blunt end into a quantity of the heads which lie before them; and catching one at the extremity, they apply them immediately to the anvil and hammer; and by a motion or two of the foot, the point and the head are fixed together in much less time than it can be described, and with a dexterity only to be acquired by practice; the spectator being in continual apprehension for the safety of their fingers' ends. The pin is now finished as to its form, but still it is merely brass; it is therefore thrown into a copper, containing a solution of tin and the leys of wine. Here it remains for some time; and when taken out assumes a white, though dull appearance: in order therefore to give a polish, it is put into a tub containing a quantity of bran, which is set in motion by turning a shaft that runs through its centre; and thus by means of friction it becomes perfectly bright. The pin being complete, nothing remains but to separate it from the bran; which is performed by a mode exactly similar to the winnowing of corn, the bran flying off, and leaving the pin behind fit for immediate sale.

PINCHBECK, an alloy containing three parts of zinc, and four of copper: it assumes the colour of gold, but it is not so malleable as brass. See ZINC.

PINE. See PINUS.

PINE-APPLE. See BROMELIA.

PINEAL GLAND. See ANATOMY.

PINGUICULA, *butterwort*, a genus of the monogynia order, in the diandria class of plants. The corolla is ringent, with a spur; calyx two-lipped, five-cleft; capsule one-celled. There are five species, of which the most remarkable is the vulgaris, or common butterwort, growing commonly on bogs or low moist grounds in England and Scotland. Its leaves are covered with soft upright pellucid prickles, secreting a glutinous liquor. The flowers are pale red, purple, or deep violet-colour, and hairy within. If the fresh-gathered leaves of this plant are put into the strainer through which warm milk from the cow is poured, and the milk is set by for a day or two to become acescent, it acquires a consistency and tenacity, and neither whey nor cream separates from it. In this state it is an extremely grateful food, and as such is used by the inhabitants of the north of Sweden. There is no further occasion to have recourse to the leaves; for half a spoonful of this prepared milk, mixed with fresh warm milk, will convert it to its own nature, and this again will change another quantity of fresh milk, and so on without end. The juice of the leaves kills lice; and the common people use it to cure the cracks or chops in cows' udders. The plant is generally supposed injurious to sheep, by occasioning in them that disease called the rot; but from experiments made on purpose, and conducted with accuracy, it appears that neither sheep, cows, goats, horses, nor swine, will feed upon this plant. Wherever this plant, called also *Yorkshire sanicle*, is found, it is a certain indication of a boggy soil. From the idea that the country-people have of its noxious operation on sheep, this plant has been called the white rot; since, as they imagine, it gives them the rot whenever they eat it, which they will not do but from great necessity.

The Laplanders, like the Swedes with the milk of cows, receive that of the rein-deer upon the fresh leaves of this plant, which they immediately strain off, and set it aside till it becomes somewhat acescent; and the whole acquires in a day or two the consistence of cream, without separating the serum, and thus becomes an agreeable food. When thus prepared, a small quantity of the same has the property of rennet in producing the like change on fresh milk.

PINGUIN, or PENGUIN, in ornithology, a genus of birds of the order of anseres, distinguished by the following characters: The bill is strong, straight, more or less bending towards the point, and furrowed on the sides: the nostrils are linear, and placed in the furrows; the tongue is covered with strong spines, pointing backwards; the wings are small, very like fins, and covered with no longer feathers than the rest of the body, and are useless in flight; the body is clothed with thick short feathers, having broad shafts, and placed as compactly as the scales of fishes; the legs are short, thick, and placed very near the vent; the toes are four, and are all placed forwards; the interior are loose, and the rest are webbed: the tail is very stiff, consisting of broad shafts scarcely webbed.

It is agreed that pinguins are inhabitants of southern latitudes only; being, as far as is yet known, found only on the coasts of South America, from Port Desire to the Straits of Magellan; and Frezier says they are found on the western shore as high as Conception. In Africa they seem to be unknown, except on a small isle near the Cape of Good Hope, which takes its name from them. They are found in vast numbers on land during the breeding-season, for they seldom come on shore but at that time: they form burrows under ground like rabbits; and the isles they frequent are perfectly undermined by them.

Their attitude on land is quite erect, and on that account they have been compared by some to pigmies, by others to children with white bibs. They are very tame, and may be driven like a flock of sheep. In water they are remarkably active, and swim with vast strength, assisted by their wings, which serve instead of fins; their food in general is fish; not but that they will eat grass like geese.

Mr. Latham remarks, that this genus appears to hold the same place in the southern division of the earth that the awks do in the northern; and that, however authors may differ in opinion on this head, they ought not to be confounded with one another. The pinguin is never seen but in the temperate and frigid zones south of the equator, while the awk only appears in the parallel latitudes north of the equator; for neither of these genera has yet been observed within the tropics.

The wings of the pinguin are scarcely any thing else than mere fins, while the awk has real wings and gills, though they are but small. The former has four toes on each foot, the latter only three. While swimming, the pinguin sinks wholly above the breast, the head and neck only appearing out of the water; while the awk, like most other birds, swims on the surface. There are several other peculiarities which serve to distinguish the two genera, but what we have mentioned are doubtless sufficient.

The bodies of the pinguin tribe are commonly so well and closely covered with feathers that no wet can penetrate; and as they are in general excessively fat, these circumstances united secure them from cold. They have often been found above 700 leagues from land, and frequently on the mountains of ice, on which they seem to ascend without difficulty, as the soles of their feet are very rough, and suited to the purpose. Mr. Latham enumerates nine different species of this genus, besides two varieties of the black-footed pinguin or diomedea.

1. The first, which is a very beautiful species, our author calls the crested pinguin. The birds of this species are twenty-three inches long; the bill is three inches long, and of a red colour; the head, neck, back, and sides, are black. Over each eye there is a stripe of pale yellow feathers, which lengthens into a crest behind, nearly four inches long. The female has a streak of pale yellow over the eye, but it is not prolonged into a crest behind as in the male.

This species inhabits Falkland Islands, and was likewise met with in Kerguelen's Land, or Isle of Desolation, as well as at Van Diemen's Land, and New Holland, particularly in Adventure-bay. They are called hopping pinguins, and jumping Jacks, from their action of leaping quite out of the water, on meeting with the least obstacle, for three or four feet at least; and indeed, without any seeming cause, they often do the same, appearing chiefly to advance by that means. This species seems to have a greater air of liveliness in its countenance than others, yet is in fact a very stupid bird, so much so as to suffer itself to be knocked on the head with a stick when on land. Forster says he found them difficult to kill; and when provoked, he adds, they ran at the sailors in flocks, and pecked their legs, and spoiled their clothes. When angered too, they erect their crests in a beautiful manner. These birds make their nests among those of the pelican tribe, living in tolerable harmony with them; and lay seldom more than one egg, which is white, and larger than that of a duck. They are mostly seen by themselves, seldom mixing with other pinguins, and often met with in great numbers on the outer shores, where they have been bred.

2. The second species mentioned by Latham is the Patagonian. It is distinguished by this name not only because it is found on that coast, but also because it exceeds in bulk the common pinguins as much as the natives are said to do the common race of men. It was first discovered by captain Macbride, who brought one of them from Falkland Islands, off the Straits of Magellan. The length of the stuffed skin of this particular bird measured four feet three inches, and the bulk of the body seemed to exceed that of a swan.

This species, which was, as we have seen, first met with in Falkland Islands, has since been seen in Kerguelen's Land, New Georgia, and New Guinea. M. Bougainville caught one, which soon became so tame as to follow and know the person who had the care of it; it fed on flesh, fish, and bread; but after a time grew lean, pined away, and died. Their chief food, when at large, is thought to be fish; the remains of which, as well as crabs, shell-fish, and molluscæ, were found in the stomach. This species is the fattest of the tribe; and therefore most so in January, when they moult. They are supposed to lay and sit in October. They are met with in the most deserted places. Their flesh is black, though not very unpalatable. This has been considered as a solitary species, but has now and then been met with in considerable flocks.

3. The Magellanic species is about two feet, and sometimes two feet and a half, long, and weighs eleven pounds. The bill is black, having a transverse band across near its tip; the head and neck are black, except a few markings here and there; the upper parts of the body and wings are of the same colour; the under parts of both are white from the breast. This species, which is very numerous, inhabits the Straits of Magellan, Staten Land, Terra del Fuego, and Falkland Islands. Far from being timid, these birds will often attack a man, and peck his legs. As food they are not at all unpalatable. They often mix with sea-wolves among the rushes, burrowing in holes like a fox. They swim with prodigious swiftness. They lay their eggs in collective bodies, resorting in incredible numbers to certain spots, which their long residence has freed from grass, and to which were given the names of towns. Penrose observes, that they composed their nests of mud, a foot in height, and placed as near one another as may be. It is possible that they may have different ways of nesting, according to the places they inhabit; or perhaps the manners of this may be blended with those of another. "Here, (says he, *i. e.* in the places they frequent) during the breeding-season, we were presented with a sight which conveyed a most dreary, and I may say awful, idea of the desertion of these islands by the human species: a general stillness prevailed in these towns: and whenever we took our walks among them, in order to provide ourselves with eggs, we were regarded indeed with side-long glances, but we carried no terror with us. The eggs are rather larger than those of a goose, and laid in pairs. When we took them once, and sometimes twice in a season, they were as often replaced by the birds; but prudence would not permit us to plunder too far, lest a future supply in the next year's brood might be prevented." They lay some time in November, driving away the albatrosses, which have hatched their young in turn before them. The eggs were thought palatable food, and were preserved good for three or four months."

PINION, in mechanics, an arbor, or spindle, in the body whereof are several notches, which catch the teeth of a wheel that serves to turn it round: or it is a lesser wheel which plays in the teeth of a larger.

PINITE, a mineral that has received its name from Pini in Saxony, where it has been found in granite. Its colour is reddish-brown, or black; always in crystals, either rhomboidal prisms, or six-sided prisms; sometimes entire; sometimes having their alternate lateral edges truncated; sometimes whole; surface smooth and brilliant; fracture uneven, passing to conchoidal; specific gravity 2.9. It melts at 153° of Wedgewood, into a black compact glass, the surface of which is reddish. It consists, according to Klaproth, of

63.00	alumina
29.50	silica
6.75	iron.
99.25	

PINK, a vessel used at sea, masted and rigged like other ships, only that this is built with a round stern; the bends and ribs compassing so as that her sides bulge out very much. This disposition renders the pinks difficult to be boarded, and also enables them to carry greater burdens than others, whence they are often used for store-ships, and hospital-ships, in the fleet.

PINK. See DIANTHUS.

PINNA, in zoology; a genus belonging to the order of vermes testacea. The animal is a slug. The shell is bivalve, fragile, and furnished with a beard; gapes at one end; the valves hinge without a tooth. They inhabit the coasts of Provence, Italy, and the Indian ocean. The largest and most remarkable species inhabits the Mediterranean. It is blind; as are all of the genus; but furnished with very strong calcareous valves. The cuttle-fish, an inhabitant of the same sea, is a deadly foe to this animal: as soon as the pinna opens its shell, he rushes upon her like a lion; and would always devour her, but for another animal whom she protects within her shell, and from whom in return she receives very important services. It is an animal of the crab kind (see CANCER), naked like the hermit, and very quick-sighted. This cancer or crab the pinna receives into her covering, and, when she opens her valves in quest of food, lets him out to look for prey. During this the cuttle-fish approaches; the crab returns with the utmost speed and anxiety to his hostess, who being thus warned of the danger shuts her doors, and keeps out the enemy. That very sagacious observer Dr. Hasselquist, in his voyage towards Palestine, beheld this curious phenomenon, which though well known to the antients, had escaped the moderns.

The pinnæ marinæ differ less from muscles in the size of their shells, than in the fineness and number of certain brown threads which attach them to the rocks, hold them in a fixed situation, secure them from the rolling of the waves, especially in tempests, and assist them in laying hold of slime. See MYTILUS. These threads, says Rondelet, are as fine, compared with those of muscles, as the finest flax is compared with tow. M. de Reaumur says, that these threads are nearly as fine and beautiful as silk from the silk-worm, and hence he calls them the silk-worms of the sea. Stuffs, and several kinds of beautiful manufacture, are made of these threads at Palermo; in many places they are the chief object of fishing, and become a silk proper for many purposes. It requires a considerable number of the pinnæ marinæ for one pair of stockings. Nothing can equal the delicacy of this singular thread. It is so fine, that a pair of stockings made of it can be easily contained in a snuff-box of an ordinary size. In 1754, a pair of gloves or stockings of these materials was presented to pope Benedict XIV. which, notwithstanding their extreme fineness, secured the leg both from cold and heat. A robe of the same singular materials was the gift of a Roman emperor to the satrap of Armenia. A great many manufacturers are employed in manufacturing these threads into various stuffs at Palermo and other places.

The men who are employed in fishing up the pinnæ mariæ inform us, that it is necessary to break the tuft of threads. They are fished up at Toulon, from the depth of 15, 20, and sometimes more than 30 feet, with an instrument called a cramp. This is a kind of fork of iron, of which the prongs are perpendicular with respect to the handle. Each of them is about eight feet in length, and there is a space between them of about six inches; the length of the handle is in proportion to the depth of the water; the pinnæ are seized, separated from the rock, and raised to the surface, by means of this instrument. The tuft of silk issues directly from the body of the animal; it comes from the shell at the place where it opens, about four or five inches from the summit or point in the large pinnæ.

PINNACE, a small vessel used at sea, with a square stern, having sails and oars, and carrying three masts, chiefly used as a scout for intelligence, and for landing of men, &c. One of the boats belonging to a great man of war, serving to carry the officers to and from the shore, is also called the pinnace.

PINNACLE, in architecture, the top or roof of a house, terminating in a point. This kind of roof, among the antients, was appropriated to temples; their ordinary roofs were all flat, or made in the platform way. It was from the pinnacle that the form of the pediment took its rise.

PINNATED LEAVES. See BOTANY.

PINUS, the *pine-tree*, a genus of the monadelphia order, in the monœcia class of plants. The male calyx is four-leaved; no corolla; stamina very many, with naked anthers; fem. cal. strobiles, with a two-flowered scale; corolla none; pistil one; nut with a membraneous wing. There are 21 species of this genus; of which the most remarkable are the following:

1. The pinea pineaster, or wild pine, grows naturally on the mountains in Italy and the south of France. It grows to the size of a large tree; the branches extend to a considerable distance; and while the trees are young, they are full of leaves, especially where they are not so close as to exclude the air from those within; but as they advance in age, the branches appear naked, and all those which are situated below become unsightly in a few years; for which reason they are now much less in esteem than formerly.

2. The pinus pinea, or stone pine, is a tall evergreen tree, native of Italy and Spain. It delights in a sandy loam, though like most others it will grow well in almost any land. Respecting the uses of this species, Hanbury tells us that "the kernels are eatable, and by many preferred to almonds. In Italy they are served up at table in their desserts. They are exceedingly wholesome, being good for coughs, colds, consumptions, &c. on which account only this tree deserves to be propagated."

3. The rubra, commonly called the Scots fir or pine. It is common throughout Scotland, whence its name, though it is also found in most of the other countries of Europe. M. du Hamel, of the Royal Academy of Sciences, mentions his having received some seeds of it from St. Domingo in the West Indies; and thence concludes, that it grows indifferently in the temperate, frigid, and torrid zones. The wood of this tree is the red or yellow deal, which is the most durable of any of the kinds yet known. The leaves of this tree are much shorter and broader than those of the former sort, of a greyish colour, growing two out of one sheath; the cones are small, pyramidal, and end in narrow points; they are of a light colour, and the seeds are small.

4. The pinus picea, or yew-leaved fir, is a tall evergreen, and a native of Scotland, Sweden, and Germany. This species includes the silver fir, and the balm of Gilead fir. The first of these is a noble upright tree. Mr. Marsham says, "The tallest trees I have seen were spruce and silver firs in the valleys in Switzerland. I saw several firs in the dock-yards in Venice 40 yards long; and one of 39 yards was 18 inches diameter at the small. I was told they came from Switzerland." The branches are not very numerous, and the bark is smooth and delicate. The leaves grow singly on the branches, and their ends are slightly indented. Their upper surface is of a fine strong green colour, and their under has an ornament of two white lines running lengthwise on each side the mid-rib; on account of which silvery look this sort is called the silver fir. The cones are large, and grow erect; and when the warm weather comes on, they soon shed their seeds, which should be a caution to all who wish to raise this plant, to gather the cones before that happens.

The balm of Gilead fir has of all the sorts been most coveted, on account of the great fragrance of its leaves, though this is not its only good property; for it is a very beautiful tree, naturally of an upright growth, and the branches are so ornamented with their balmy leaves as to exceed any of the other sorts in beauty.

The silver fir is very hardy, and will grow in any soil or situation, but always makes the greatest progress in rich loamy earth. The balm of Gilead fir must be planted in deep, rich, good earth; nor will it live long in any other. The soil may be a black mould, or of a sandy nature, if it is deep enough, and if the roots have room enough to strike freely.

5. The pinus abies, or European spruce fir, a native of the northern parts of Europe and Asia, includes the Norway spruce and long-coned Cornish fir. The former of these is a tree of as much beauty while growing, as its timber is valuable when propagated on that account. Its growth is naturally like the silver, upright; and the height it will aspire to may be easily conceived, when we say that the white deal, so much coveted by

the joiners, &c. is the wood of this tree; and it may perhaps satisfy the curious reader to know, that from this fir pitch is drawn. The leaves are of a dark-green colour; they stand singly on the branches. They are very narrow, their ends are pointed, and they are possessed of such beauties as to excite admiration. The cones are eight or ten inches long, and hang downwards.

6. The pinus Canadensis, American or Newfoundland spruce fir, a native of Canada, Pennsylvania, and other parts of North America, includes three varieties; the white Newfoundland spruce, the red Newfoundland spruce, and the black Newfoundland spruce. These, however, differ so little, that one description is common to them all. They are of a genteel upright growth, though they do not shoot so freely, nor grow so fast, with us, as the Norway spruce.

7. The pinus balsamea, or hemlock fir, a native of Virginia and Canada, possesses as little beauty as any of the fir tribe; though, being rather scarce in proportion, it is deemed valuable. It is called by some the yew-leaved fir, from the resemblance of the leaves to those of the yew-tree. It is a tree of low growth, with but few branches; and these are long and slender, and spread abroad without order. The cones are very small and rounded; they are about half an inch long, and the scales are loosely arranged. We receive these cones from America, by which we raise the plants; though this caution should be given to the planter, that this tree is fond of moist rich ground, and in such a kind of soil will make the greatest progress.

8. The pinus Orientalis, or Oriental fir, a native of the East, is a low but elegant tree. The leaves are very short, and nearly square. The fruit is exceedingly small, and hangs downward; and the whole tree makes an agreeable variety with the other kinds.

9. The strobus, lord Weymouth's pine, or North American white pine, grows sometimes to the height of 100 feet, and upwards, and is highly valued on account of its beauty. The bark of the tree is very smooth and delicate, especially when young; the leaves are long and slender, five growing out of one sheath, and thus make a fine appearance. The cones are long, slender, and very loose, opening with the first warmth of the spring; so that, if they are not gathered in winter, the scales open, and let out the seeds. The wood of this sort is esteemed for making masts for ships. In queen Anne's time there was a law made for the preservation of these trees, and for the encouragement of their growth in America. Within these last 50 years they have been propagated in Britain in considerable plenty.

The soil the Weymouth pine delights in most is a sandy loam; but it likes other soils of an inferior nature, although it is not generally to be planted on all lands like the Scotch fir. On stony and slaty ground, likewise, there are some very fine trees; so that whoever is desirous of having plantations of this pine, need not be too curious in the choice of his ground.

10. The pinus tæda, or swamp-pine, is a tall evergreen tree, a native of the swamps of Virginia and Canada. There are several varieties of this genus which Hanbury enumerates and describes, such as, 1st, The three-leaved American swamp-pine. 2d, The two-leaved American pine. 3d, The yellow American pine, the yellow tough pine, and the tough pine of the plains; among which there is but little variety. 4th, The bastard pine. 5th, The frankincense pine. 6th, The dwarf pine.

11. The pinus cedrus is that popularly called by us the cedar of Lebanon; by the antients cedrus magna, or the great cedar. It is a coniferous evergreen, of the bigger sort, bearing large roundish cones of smooth scales, standing erect, the leaves being small, narrow, and thick-set. They sometimes counterfeit cedar, by dying wood of a reddish hue: but the smell discovers the cheat, that of true cedar being very aromatic. In some places, the wood of the cajou tree passes under the name of cedar, on account of its reddish colour and its aromatic smell, which somewhat resemble that of santal. Cedar wood is reputed almost immortal and incorruptible; a prerogative which it owes chiefly to its bitter taste, which the worms cannot endure. For this reason it was that the ancients used cedar tablets to write upon, especially for things of importance, as appears from that expression of Persius, "Et cedrâ digna locutus." A juice was also drawn from cedar, with which they smeared their books and writings, or other matters, to preserve them from rotting.

Solomon's temple, as well as his palace, were both of this wood. "The statue (says Hanbury) of the great goddess at Ephesus was made of this material; and if this tree abounded with us in great plenty, it might have a principal share in our most superb edifices." It is remarkable that this tree is not to be found as a native in any other part of the world than mount Libanus, as far as has yet been discovered. What we find mentioned in Scripture of the lofty cedars, can be nowise applicable to the common growth of this tree; since, from the experience we have of those now growing in England, as also from the testimony of several travellers who have visited those few remaining trees on mount Libanus, they are not inclined to grow very lofty, but on the contrary extend their branches very far.
